Aniline Black. II. R. Wüstätter and S. Dorog, Ber., 1909, 42, 2147—2168. (Compare this J., 1907, 755.)

THE authors discuss first the oxidation of aniline to quinone. They show that in this process phenylhydroxylamine can play no part for it does not yield quinone on oxidation with bichromate and sulphuric acid but only nitrosobenzene. In oxidising aniline with this oxidising mixture, Aniline Black is the first intermediate product and this is then further oxidised to quinone. This Aniline Black contains no oxygen and is no derivative of phenylhydroxylamine or aminophenol; as a matter of fact neither of these gives Aniline Black. Neither is it possible that phenylhydroxylamine is formed and then condenses with aniline to aminodiphenylamine as Nover suggested (this J., 1907, 145), for (1) the latter compound, when oxidised with bichromate and sulphuric acid gives mostly Emeraldine which is not produced in oxidising aniline by the same means; (2), aminodiphenylamine gives with bichromate and sulphuric acid only about 60 per cent. of quinone under the same conditions in which aniline gives more than 85 per cent. of quinone; and (3), in a mixture of phenylhydroxylamine and aniline a mixture of bichromate and sulphuric acid oxidises first the former to nitrosobenzene and then the latter to Aniline Black. With regard to the actual formation of quinone from Aniline Black, by oxidation with bichromate and sulphuric acid under Nietzki's conditions, the authors have obtained 88—89 per cent. of the theoretical amount of quinone; about one-eighth part is thus lost. When however the necessary amount of bichromate for producing Aniline Black is added to aniline sulphate and then oxidation by lead peroxide is effected, the remarkable fact has been discovered that the yield of quinone is now increased to 95 per cent. of the theoretical amount, which is as much as is obtained by the oxidation of *p*-phenylenediamine or *p*-aminophenol. This is considered to prove that the leuco-compound of Aniline Black consists of the indamine chain, $C_6H_5.NH.[C_6H_4.NH]_6.C_6H_5.NH_2$.

A molecular-weight determination of Aniline Black has been carried out by hydrolysing it with dilute sulphuric acid. By this operation one-eighth part of the nitrogen is evolved as ammonia thus:—

The Black produced is of a much deeper colour than the original substance. Further the composition of the Aniline Black produced by the cold oxidation of aniline with bichromate and sulphuric acid has been investigated and it is found that: (1), for 1 mol. of aniline, 1.27 atoms of oxygen are required, the formula of the authors ($C_6H_4.4N$), requiring 1.25 atoms; (2), the maximum yield (97 per cent. of the theory) is obtained by using $1\frac{1}{4}$ atoms of oxygen; and (3), repeated analyses agree with the composition $C_6H_4.5N$. From these facts the authors conclude that the constitution of Aniline Black is:—

the position of the internal quinonoid linking being arbitrarily selected.—J. C. C.

1-Methoxy-4-aminobenzene-2-sulphonic acid. R. Bauer. Ber., 1909, 42, 2106—2111.

p-ANISIDINE (10 grms.) is added to 20 c.c. of cold, concentrated sulphuric acid and when all is dissolved, 22 c.c. of fuming sulphuric acid (containing 20 per cent. of sulphur trioxide), are added and the whole warmed for 15—20 minutes at 55° C. On pouring on ice, the sulphonic acid is precipitated and is purified by crystallising from water. This acid has been proved to be 1-methoxy-4-aminobenzene-2-sulphonic acid by methylating the known 1-hydroxy-4-aminobenzene-2-sulphonic acid (through the benzylidene derivative) when the two preparations were found to be identical. The diazo-compound of this anisidinesulphonic acid is well crystallised and gives a blood-red dyestuff with β -naphthol. —J. C. C.

meri-Quinone-imines. III. R. Willstätter and J. Piccard. Ber., 1909, 42, 1902—1907

WHEN a dilute solution of *p*-aminophenol hydrochloride (1.45 grms.) is oxidised in the cold with half the theoretical amount of ferric chloride (161 grms.), a violet dyestuff, $C_{12}H_{10}O_2N_2.HCl$, is precipitated which is very unstable. On reduction with stannous chloride it yields a leucobase which is 5 (or 2)-amino-2(or 5) : 4-dihydroxydiphenylamine. On oxidation with chromic acid this leuco-compound yields benzoquinone. —J. C. C.

Triphenylmethane dyestuffs; Substituted —. H. Finger. J. prakt. Chem., 1909, 79, 492—497.

TRICHLOROMAGENTA is prepared from methylenedi-*o*-chloroaniline by first converting this into *pp'*-diamino-*mm'*-dichlorodiphenylmethane by heating it with *o*-chloroaniline and the hydrochloride of the latter in alcoholic solution for 8 hours under a reflux condenser. The dihydrochloride of the base melts at 201° C. This base is heated with *o*-chloroaniline, the hydrochloride of the latter, and arsenic acid, thereby being transformed into Trichloromagenta. The dyestuff forms a dark red powder with a metallic green reflex. The dyeings obtained are slightly brighter than those produced by New Magenta. For the preparation of Trimethoxy-*p*-magenta, *pp'*-diamino-*mm'*-dimethoxydiphenylmethane, obtained from methylenedi-*o*-anisidine is converted into the diacetyl derivative; this is oxidised with potassium bichromate and sulphuric acid to diacetyldiaminodimethoxybenzophenone and, after eliminating the acetyl groups, this is reduced with sodium amalgam in alcoholic solution to diaminodimethoxydiphenylcarbinol; or diaminodimethoxydiphenylmethane or methylenedi-*o*-anisidine is heated with *o*-anisidine hydrochloride, *o*-nitroanisole, and ferric chloride when Trimethoxy-*p*-magenta is obtained. It forms a copper coloured mass with a green reflex and the dyeings obtained from it are more violet than those produced by New Magenta. —J. C. C.

Coal-tar dyestuffs; Manufacture of — in the United States. J. F. Schoellkopf. Seventh Int. Congr. Appl. Chem., London, 1909.

THE reasons for the retarded growth of the coal-tar dyestuff industry in the United States, which, prior to the Tariff Act of 1883, was in a flourishing condition, is considered to be due to the unfavourable tariff legislation of 1883, when no less than five distinct coal-tar dyestuffs factories retired from the field. The Tariff Act of 1897, however, made progress in the United States possible, and in the ten years next succeeding, the industry made greater strides than it had in the preceding 30 years. With a prospect of better tariff protection and of suitable modification of the Patent Laws, combined with a renewed supply of suitable coal-tar hydrocarbons to be obtained by the new systems of coking coal now being adopted in the United States, it seems not at all impossible that the United States may, in the course of time, become exporters of coal-tar dyestuffs instead of being importers.

Aside from alizarin and anthracene colours, which have been duty-free, the list of dyestuffs manufactured is fairly complete. American needs of Magentas, Chrysoidines, Bismarck Browns, Aniline Blues, Nigrosines, and the like are practically supplied by makers in the United States;

large quantities of direct cotton dyestuffs, Acid Blacks, Acid Reds, and Acid Blues are also made in the United States.

The total output of coal-tar dyestuffs made in the United States is placed at 4,000,000 pounds, valued at considerable above 1,000,000 dols., and for the last ten years the rate of increase in domestic production has been about twice as great as the rate of increase in importations.

Alcohol; Tax-free denatured grain — in the manufacture of coal-tar dyestuffs in the United States. G. A. Prochazka. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author states that the use of tax-free denatured alcohol made possible by United States legislation in force since January 1st, 1907, has had no effect on the manufacture of coal-tar colours within the United States; this he ascribes to the regulations established by the Commissioner of Internal Revenue in order properly to protect the revenue, and characterises them as cumbersome, inquisitorial, annoying and not at all feasible, and as making the use of the tax alcohol preferable to the use of the denatured alcohol under such restrictions.

Dyestuffs derived from gallic acid. E. Ehrmann. Seventh Int. Congr. Appl. Chem., London, 1909.

WHEN gallic acid is condensed with diphenyl-*m*-phenylenediamine, a dyestuff is produced which gives blue shades on cotton mordanted with iron, aluminium, or chromium. From gallic acid and *m*-hydroxydiphenylamine a dyestuff of similar properties is obtained, but the shades produced are red. —J. C. C.

Paranitrosomethylaniline; a new intermediate product for the manufacture of dyestuffs. J. C. Cain. Seventh Int. Congr. Appl. Chem., London, 1909.

IN view of the very extensive use of paranitrosodimethylaniline in the colour industry it is surprising that the corresponding derivative of methylethylaniline has not yet been described. *p*-Nitrosomethylethylaniline, $NO_2.C_6H_4.N(CH_2CH_3)_2$, is readily prepared by treating methylethylaniline hydrochloride with nitrous acid as in the case of the analogous dimethyl compound. The hydrochloride forms yellow needles, and the free base crystallises from dilute alcohol in green plates melting at 66°—67°. The author is engaged in studying the reactions of this compound. Paranitrosomethylethylaniline can obviously be used in the manufacture of a large number of dyestuffs, and as an example of these the author has prepared the corresponding Methylene Blue in which the dimethyl groups of ordinary Methylene Blue are replaced by the methylethyl groups. This new dyestuff may conveniently be called Methylene Blue M.E. (i.e., methylethyl); it dyes tannin-mordanted cotton in shades which are much greener than those produced by ordinary Methylene Blue.

Monoacetyl derivatives of diamines of the benzidine type. Preparation of —. J. C. Cain. Seventh Int. Congr. Appl. Chem., London, 1909.

THE monoacetyl derivatives of benzidine, tolidine, dianisidine and dichlorobenzidine (of which the first was obtained in very small yield by Schmidt and Schuch in 1879 (Ber., 12, 489), can very readily be prepared in good yield by treating a cold dilute alcoholic solution of the base with acetic anhydride. One molecular proportion of acetic anhydride is added to one molecular proportion of the dissolved base, the solution is neutralised with ammonia, filtered hot (from any diacetyl compound), and water added until a turbidity is produced when, on cooling, the pure monoacetyl compound separates. Under the conditions benzidine yields about 2 parts of the monoacetyl to 1 of the diacetyl derivative, tolidine about 3 to 1, dichlorobenzidine, mostly monoacetyl, with very little of the diacetyl compound, and dianisidine gives only the monoacetyl derivative. Monoacetyltolidine, $CH_3.CO.NH.C_6H_3(NH_2)_2.H_2O$, has already been described by the author (Trans. Chem. Soc., 1909, 95, 714). The following compounds are here described for the first time. Monoacetyldianisidine, $CH_3.CO.NH.C_6H_3(H_2O.NH_2)_2$, is readily soluble in alcohol and crystallises from water

hite nodules, m.p. 67°. The water of crystallisation is lost at 100° and the anhydrous substance melts at 116°. 3:3'-*ichloromonoacetylbenzidine*, $\text{CH}_3\text{CO.NH.C}_{12}\text{H}_6\text{Cl}_2\text{.NH}_2$, dissolves easily in alcohol but sparingly in water, and forms feathery crystals m.p. 104°—105°. 3:3'-*Dichlorodiacylbenzidine*, $\text{C}_{12}\text{H}_6\text{Cl}_2\text{(NH.CO.CH}_3\text{)}_2$, crystallises from glacial acetic acid in fine white needles, m.p. 302°.

The ready production of the above monoacetyldiamines makes it now possible to obtain asymmetrical diazo-estuffs or other compounds in the preparation of which an exact "half-diazotisation" of the diamines is necessary, an acetyl group being hydrolysed after the combination of the first component. It is well known that the "half-diazotisation" of benzidine, etc., cannot be satisfactorily accomplished.

Triphenylcarbinol and tritolylcarbinol; Action of amines on —. A. G. Green and A. E. Woodhead. Seventh Int. Congr. Appl. Chem., London, 1909.

THERE are considerable grounds for regarding the so-called phenylation" of rosaniline salts, on heating with aniline, as a typical "quinonoid" reaction consisting in the direct lifting off of a quinonimide group and replacement by a quinylimino-group. Upon this view the trimethoxyd trihalogen derivatives of triphenylcarbinol, which also readily give rise to Aniline Blue on heating with aniline, could likewise be regarded as reacting in their quinonoid state:

- (a) $\text{R}_3\text{C:C}_6\text{H}_4\text{:NH}_2\text{Cl}$.
- (b) $\text{R}_3\text{C:C}_6\text{H}_4\text{:O(CH}_3\text{)}_3\text{Cl}$.
- (c) $\text{R}_3\text{C:C}_6\text{H}_4\text{:I.Cl}$.

In view of the possible quinonoid structure of the coloured salts of triphenylcarbinol itself, this body was omitted to the action of aniline and of other bases in the presence of their hydrochlorides. On heating triphenylcarbinol with aniline (two parts) and aniline hydrochloride (six parts) for ten or twelve hours at 180° a deep red melt was obtained, from which, however, only a small quantity of dyestuff could be isolated, the main product of the reaction being the aminotetraphenylthane of Ullmann and Münzhuber (Ber., 36, 407). The properties of the product do not correspond to those of a triphenylmethane colouring matter, but to a dyestuff of the Induline class. It appears, therefore, that an reduction of the phenylimino-group does not occur; that the triphenylcarbinol merely acts as an oxidising agent on the aniline. This is confirmed by the fact that paratoluidine is substituted for aniline, no colouration occurs. On the other hand, orthotoluidine gives a red very similar to Magenta, and dimethylaniline a violet similar to Methyl Violet. Triparatolylcarbinol is found to give quite similar reactions with the reactive amines. In all cases the yield of dyestuff is small.

Sanderswood; Colouring matter of —. J. C. Main and P. May. Seventh Int. Congr. Appl. Chem., London, 1909.

SANDERSWOOD, the colouring matter contained in red sanderswood (*Petrocapus santalinus* L.) has the formula, $\text{C}_{15}\text{H}_{11}\text{O}_5$, contains one methoxyl group.

Dyestuffs in aqueous solution; Condition on some —. L. Knecht and J. P. Batey. Seventh Int. Congr. Appl. Chem., London, 1909. (See also J. Soc. Dyers and Col., 1909, 25, 194–203.)

IN the present work a number of dyestuffs have been prepared in a state of purity, and the conditions of their aqueous solutions examined by determinations of their electrical conductivities, ebullioscopic determinations of molecular weights, and experiments in simple diffusion. Direct cotton colours investigated were Benzopurpurine B, Erika B, and Chrysophenine. The other dyestuffs used were Soluble Blue (free sulphonic acid) and Methyl Yellow S. The electrical conductivities of aqueous solutions of these substances, measured at 15° and 18°, showed that they behaved as normal electrolytes, being highly dissociated in weak solutions.

Similarly, the determinations of their molecular weights by the boiling point method indicated that dissociation was taking place.

Experiments with solutions of the above dyestuffs showed that they all possessed the property of diffusing into pure water, in the absence of a diaphragm. Comparative tests on the rate of diffusion of picric acid, Benzopurpurin and Soluble Blue indicated that the two latter compounds were dissociated and non-colloidal. Positive and corroborative evidence is thus adduced to prove that the aqueous solutions of the dyestuffs experimented with are not colloidal in character.

Dyes in solution; State of certain —. S. E. Sheppard. Seventh Int. Congr. Appl. Chem., London, 1909.

(a) IN the aqueous solutions of certain dyestuffs—Isocyanine, Pinacyanol, Cyanine—the dyestuff is present partially or wholly in colloid solutions, and the absorption spectrum differs markedly from that of a true solution. (b) In other aqueous solutions of dyestuffs, the change from true to colloid solution is accompanied by a broadening and diffusion of the absorption band, due to increase in number and size of the particles, a physical change greatly modifying the absorption. Deviations from Beer's law result. (c) The state of dyestuffs in solid media is comparable to that in liquids, and the absorption spectrum may in many cases be used as a criterion. (d) The solution of dyestuffs appears to be due to a combined process of disaggregation of the solute—the dyestuff—accompanied by a progressively increasing combination with the solvent. If the same state of solution be attained in different solvents, the absorption maxima are displaced in accordance with Kundt's law.

PATENTS.

Disazo-dyestuff; Manufacture of a —. Act.-Ges. f. Anilinfabr., Berlin, Germany. Eng. Pat. 7905, Apr. 2, 1909. Under Int. Conv., Apr. 14, 1908.

A DISAZO-DYESTUFF can be made by combining one molecular proportion of the diazo-derivative of *p*-aminophenylarsinic acid with one molecular proportion of 1:8:3:6-aminonaphtholdisulphonic acid in acid solution, and then combining the intermediate product thus obtained with another molecular proportion of the diazo-derivative of *p*-aminophenylarsinic acid in alkaline solution. There is thus obtained a blue dyestuff easily soluble in water which is useful in medicine.—P. F. C.

Thioaniline sulphonic acids; Process for preparing —. Act.-Ges. f. Anilinfabr. Ger. Pat. 210,564, July 21, 1907.

p-NITROCHLOROBENZENESULPHONIC acid is condensed with *p*-nitrothiophenol or one of its sulphonic acids in alkaline solution; the dinitrodiphenylsulphide sulphonic acids thus obtained are converted into the corresponding sulphonic acids of thioaniline by reduction, e.g., with zinc dust in alkaline solution.—T. F. B.

Dyestuffs; Manufacture of —. R. B. Ransford, London. From L. Cassella und Co., Frankfurt-on-Maine, Germany. Eng. Pat. 20,709, Oct. 1, 1908.

IF sulphonic acids of carbazole (preferably the disulphonic acid), are condensed with tetraalkyldiaminodiphenylcarbinol, valuable green acid dyestuffs are obtained. Example: 8.5 kilos. of carbazole are introduced into 90 kilos. of sulphuric acid monohydrate at the ordinary temperature and the solution is heated to about 90° C. until a sample is completely soluble in water. The mixture is then cooled to 20° C. and 13.5 kilos. of tetramethyldiaminodiphenylcarbinol are added and the whole is heated to 50° C. until the latter has disappeared. The mixture is then cooled and stirred into 45 kilos. of ice and 90 litres of water. The leucosulphonic acid separates in colourless needles which are filtered off, washed and dried. To obtain the dyestuff, the leuco-

compound is dissolved in water together with the necessary quantity of sodium hydroxide and firstly lead peroxide and then acetic acid are added to the well-cooled and briskly stirred solution. When the oxidation is complete, the lead is precipitated as sulphate and the dyestuff is separated in the usual manner. It dissolves in hot alcohol with a bluish-green colour and in concentrated sulphuric acid with a pure yellow colour. In an acid bath, wool is dyed a green shade fast to alkali; the baths are completely exhausted.—P. F. C.

Vat dyestuff; Red —, and process of making same. G. Engli, Assignor to Soc. Chim. Ind. in Basle, Switzerland. U.S. Pat. 923,959, June 8, 1909.

A RED vat dyestuff is obtained by boiling one molecule of a derivative of phenylthioglycol-*o*-carboxylic acid with one molecule of an acetyl derivative of isatin, in the presence of a condensing agent capable of transforming the phenylthioglycol-*o*-carboxylic acid derivative into an intermediate oxythionaphthene compound. The shades produced by the dyestuff are fast to washing, light and chlorine.—J. C. C.

Anthraquinone series; Production of various of the —. Soc. pour l'Ind. Chim. a Basle. Fr. Pat. 397,444, Feb. 24, 1908.

By treating mono- and di-aminoanthraquinones with carbonyl chloride, corresponding ureas are produced which are vat dyestuffs giving fast yellow, gray and brown shades. The operation is carried out by passing carbonyl chloride into a solution of the amine in nitrobenzene at the boiling point. If a mixture of two different aminoanthraquinones is employed in molecular proportions, a mixed dianthraquinoylurea is produced.—J. C. C.

Dyestuffs [Azo] insoluble in water; Production of —. Badische Anilin und Soda Fabrik. First Addition, dated Dec. 5, 1908 (Under Int. Conv., March 2 and Aug. 31, 1908), to Fr. Pat. 373,475 of Jan. 11, 1907.

THE lakes described in the chief patent (this J., 1907, 680) are not entirely insoluble in oil and it has now been found that if the amines there mentioned are replaced by 2-chloro-5-nitro-*p*-toluidine, 6-chloro-4-nitro-*m*-toluidine, or 4:5-dichloro-*o*-nitraniline, the lakes produced are not only extremely fast to light, heat, alcohol, lime, etc., but are absolutely insoluble in oil. 6-Chloro-4-nitro-*m*-toluidine is prepared by nitrating 6-chloroaceto-*m*-toluidide and subsequent saponification. It is easily separated from the 6-chloro-2-nitro-*m*-toluidine which is formed at the same time, as it is less soluble in alcohol. It crystallises in brown yellow prisms melting at 158°—159° C.—J. C. C.

Dyestuffs dyeing cotton direct; Process for the production of —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 397,613, Dec. 18, 1908. Under Int. Conv., Feb. 18, 1908.

DYESTUFFS dyeing cotton direct are prepared by combining the tetrazo-derivative of a paradiamine with one molecular proportion of a 1-acetyl-amino-8-naphthol-mono-, di- or poly-sulphonic acid and with one molecular proportion of a monoacetylated metadiamine in which the para-position with regard to the free amino-group is free. The dyestuffs can be diazotised and developed on the fibre, furnishing pure blue shades which are discharged by hyposulphite (hydrosulphite) to a pure white. In the example given, the tetrazo-derivative of dianisidine is combined with one mol. of 1-acetyl-amino-8-naphthol-4:6-disulphonic acid and with one mol. of 4-acetyl-amino-2-aminotoluene. This dyestuff gives violet shades on cotton which when diazotised on the fibre and developed with β -naphthol are transformed into greenish-blue.—J. C. C.

Monoazo dyestuffs; Process for preparing mordant —. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 210,597, Feb. 20, 1908.

MORDANT-DYEING azo dyestuffs are obtained by combining the diazo compounds of such *o*-aminophenol or *o*-amino-

cresol derivatives as contain nitro groups or halogens or both, but not sulphonic or carboxylic acid groups with alkyl or aryl derivatives of *m*-aminophenol or *m*-aminocresols. Seventeen such dyestuffs are described which produce shades on chromed wool varying from red to brown and black.—T. F. B.

Pentabromindigo; Manufacture of — and of an intermediate product. O. Imray, London. From Farbwerke vorm. Meister, Lucius, und Brünig, Höchst on Maine, Germany. Eng. Pat. 13,789, June 29, 1908. SEE Fr. Pat. 392,638 of 1908; this J., 1909, 17.—T. F. B.

Indigo white or a substitution product thereof; Manufacture of brominated derivatives from —, and of dyestuffs from such derivatives. Farbwerke vorm. Meister, Lucius, und Brünig, Höchst on Maine, Germany. Eng. Pat. 18,023, Aug. 27, 1908. Under Int. Conv. Aug. 31, 1907.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

Colloidal state; Recent developments of the theory of — and their bearing on the dyeing and cleaning of textile fibres. E. Feilmann. J. Soc. Dyers and C., 1909, 25, 158—160.

THE distinction between colloidal and crystalline chemical compounds is becoming untenable; it was formerly

considered to be a characteristic of colloids that they could not diffuse through a semipermeable membrane, as crystalloids would, but Bechhold and others have shown that such membranes can be graded so well so that "colloids" can be separated from one another according to the size of their particles and other factors. According to von Weimarn all matter is essentially crystalline, a view which he has supported by much experimental evidence. H. Wislicenus has prepared aluminium hydroxide and oxide in a fibrous form which shows most of the essential properties of the natural fibres, including their strong adsorptive power. Pelet-Jolivet and Wild (this J., 1908, 1106) have shown that dyestuffs in solution are ionised electrolytes, containing large organic dyestuff ions and small inorganic ions. V. Spring (this J., 1909, 430) in a study of the cleansing action of soaps, shows that soap solutions, especially at certain definite concentrations, form suspensions with defatted, finely divided charcoal and other materials which can be filtered unchanged through ordinary filter paper. The soap appears to exercise a kind of "peptonising" action, and is itself partially decomposed into more acid and more basic portions. It may be supposed, in accordance with the views of Pelet-Jolivet and Andersen (this J., 1908, 1149), that in the process of dyeing the colour ions are attracted by the oppositely charged fibre, which may be considered to be built up of ultimate crystalline particles felted together with their crystalline axes promiscuously arranged: the dye liquor, carrying the colour ions, will penetrate this network. The forces of attraction may be pictured as sufficient to enable the colour ions to penetrate deeply into the fibre substance, where they are surrounded by the fibre particles. They may be supposed to be retained there either because the fibre substance acts as a protective colloid or because the neutralisation of the electric charges is accompanied by chemical action between dyestuff election and fibre substance.—E. F.

Indigo; Further notes on the determination of — in dyed cotton fabrics. E. Knecht. J. Soc. Dyers and Col., 1909, 25, 160—161.

THE method recently described (this J., 1909, 518) for the determination of indigo in dyed cotton fabrics, had the disadvantage that the amount of time required for the filtration of the precipitated indigotin varied considerably. This difficulty has now been overcome by diluting the solution of the fabric in sulphuric acid with four times its volume of water and boiling for a few minutes. The precipitated indigotin then becomes granular and can be filtered in from 5 to 10 minutes by the use of a filter-bed about one-third of an inch thick made from a layer of coarsely crushed quartz of about the size of millet seeds, covered by a layer of finer quartz of about the size of grain sugar, and lastly by a layer of finely-divided silica. It is not necessary to use the filter pump at first, but a light vacuum is employed later, and finally the full action of the pump is required. The whole estimation can thus be performed in a little more than two hours. The liquid obtained on boiling the dilute acid solution often becomes dark-coloured, but there is no loss of indigotin, and the colour is probably due to caramel. It is best to make the solution of indigotinsulphonic acid alkaline with sodium carbonate and then acidify with tartaric acid before titrating with titanous chloride. Titration with permanganate is not quite satisfactory. Direct cotton colours are sometimes present on the fabric. Diamine Black 3H is destroyed on sulphonation, leaving a brown precipitate on dilution which is filtered off; any further decomposition products which may be present in the filtrate do not affect the result. Columbia Black and Benzopurpurin 4B are completely precipitated on dilution after sulphonation, and can be filtered off. Other colours, such as Diamine Sky Blue and Diaminogene may interfere; in case direct cotton colours have been detected it is best to wash the precipitated indigotin with dilute ammonia, which removes them completely. This method does not apply to direct colours which have been diazotised and developed on the fibre.—E. F.

Bromindigo FB: [Dyeing with —]. R. WETTER. Färber-Zeit., 1909, 20, 185—186.

BROMINDIGO FB is a level dyeing colour, the shades obtained being equal as regards fastness to alkali, washing, etc., to those obtained with indigo. The stock solution may be prepared by reducing the dyestuff with alkaline hydrosulphite, at a temperature of about 60° C.; it is added to the dye-vat (to which a little alkaline hydrosulphite has been previously added), and the material is then entered. The colour of the vat and the material therein should be golden-yellow. Dark shades on yarn are easily dyed at about 60° C., but for light shades it is advisable to commence dyeing at 30° C., and raise the temperature gradually to 50—60°. Level, well penetrated dyeings are obtained from the hot vat and this exhausts well. Piece goods may be dyed on the jigger, extra quantities of hydrosulphite being required when the ordinary form of jigger is employed. After dyeing, the goods are squeezed, oxidised, soured, rinsed, and soaped. Bromindigo FB dyes well in combination with sulphide dyestuffs; it is reduced by boiling with a solution of caustic soda and dextrin and dyeing is carried out in a hot bath, with the addition of salt, the goods being afterwards squeezed, oxidised, soured, rinsed, and soaped. This process gives good results with half-linen and linen. Wool and silk are dyed in the hydrosulphite vat, the exhaustion being so good that it is advisable to dye at a moderately low temperature and in a "long" vat.—F. M.

Paranitro-orthoanisidine; The nitrosamine of —, and its application. C. DZIEWONSKI, W. PHUZANSKI and E. KOPEC. Sealed notes Nos. 1748, 1749, 1752, 1763, 1770, and 1831. Deposited July 11, 1907 to April 14, 1908. Bull. Soc. Ind. Mulhouse, 1909, 79, 169—174.

By substituting paranitro-orthoanisidine for parnitraniline, in the method of the Badische Anilin und Soda Fabrik (Ger. Pat. 81,791) for producing a red without a preliminary preparation of the material with β -naphthol, a much brighter and bluer shade is obtained. By pouring the solution of the diazotised base into caustic soda (in slight excess), the nitrosamine is precipitated as a greenish coloured, voluminous, microcrystalline substance; it is stable in the presence of the excess of caustic soda and may be purified by recrystallisation from hot water. In alkaline solution it does not react with phenols. The addition of the oxides of zinc or aluminium to the printing paste retards the development of the colour, but excellent results are obtained with sodium aluminate. The printing paste contains β -naphthol, caustic soda, sodium sulphurinate, sodium aluminate, nitrosamine, and sodium acetate, with gum tragacanth as thickening. After printing, the goods are dried, left to lie for a few hours in the air, and then passed through a warm bath of acid. Good results are obtained with the colour as a reserve under Aniline Black and, by mixing sodium bichromate with the printing paste, bright red discharge effects are produced on indigo-dyed cloth.—F. M.

Paranitro-orthoanisidine; The nitrosamine of — and its application on unprepared white and indigo-dyed material. E. Bourcart. Sealed note 1798. Deposited Jan. 2, 1908. Bull. Soc. Ind. Mulhouse, 79, 175—178.

THE nitrosamine is prepared by precipitating a cooled 10 per cent. solution of diazotised paranitro-orthoanisidine with cold caustic soda. It is better adapted for use upon material which has not previously been prepared with β -naphthol than is the nitrosamine of parnitraniline: mixed with Turkey red oil, β -naphthol, and a slight excess of caustic soda and printed (with gum tragacanth), the red is partially developed upon drying, apparently by the absorption of the excess of caustic soda by the cotton. The addition of castor oil to the paste assists the development as, upon drying on the fibre, the excess of caustic soda saponifies the oil and the soap produced does not retard the formation of the colour. Other substances which may be employed are potassium ethyl sulphate, chloroform, carbon tetrachloride, acetanilide, sodium thiosulphate, etc. For a coloured indigo discharge, sodium bichromate is added to the printing paste and

after the colour has been developed by drying and light steaming, the material is passed through acid, rinsed and dried.

In a report on the above communication, C. Favre draws attention to the similarity of the above method with that of Dziewonski (see preceding abstract). Both methods give good results, producing a beautiful red.

—F. M.

Cellulose: Action of oxalic acid on — E. Knecht. Seventh Int. Congr. Appl. Chem., London, 1909.

It is known that if a strong solution of oxalic acid, thickened with British gum, is printed on calico and allowed to dry at the ordinary temperature, and the calico be then well washed, the printed parts, while not being tendered, exhibit a marked affinity for Methylene Blue and a decreased affinity for direct colours like Erika. Tartaric and citric acids do not show this behaviour. The author shows that the portions which had been printed with oxalic acid lose their characteristic properties after the fabric has been boiled for a few minutes in dilute caustic soda. No oxalic acid could be detected in the caustic soda extract, so that formation of an oxalate of cellulose is not the cause of the phenomenon. Further investigation showed, however, that the caustic soda contained formic acid, which appears to be formed by the decomposition of the oxalic acid, and to act on the cellulose in the nascent state, yielding formyl-cellulose. Malonic acid acts similarly, yielding acetyl-cellulose, while the action of hexylmalonic acid is still more pronounced. It appears probable that all the acids of this series will behave similarly, and that a new mode of formation of acidic derivatives of cellulose is thus rendered available. Succinic and glutaric acids do not produce the effect.

Wool: Influence of preparing and bleaching agents on dyed — T. Valette. Seventh Int. Congr. Appl. Chem., London, 1909.

The effect of lime, ammonia, sodium carbonate, soap, hydrogen peroxide, sulphurous acid, and hypochlorous acid on the shades produced on wool hanks with acid dyestuffs, chrome- and alumina-mordant dyestuffs and indigo, was investigated. Lime and hypochlorous acid gave the most beautiful shades and manifested the greatest affinity for the colours. The depths of shade obtained in the case of sodium carbonate, soap, and ammonia were much less, while the duldest shades were those obtained with the last-named. Hydrogen peroxide gave still less depth, and sulphurous acid produced the clearest shades. Inert colours such as ultramarine or madder, suspended in cold water, were taken up energetically by the chlorinated wool, whilst wool treated with lime or sodium carbonate was scarcely coloured. Hanks treated with the above reagents and dyed to equal shades with each colour, on exposure to sunlight for three months, all faded practically to the same degree, except that the chlorinated wool appeared to be slightly less fugitive.—H. P. P.

Logwood and its secondary functions. P. Heermann. Seventh Int. Congr. Appl. Chem., London, 1909.

In addition to its tinctorial properties Logwood exerts an important influence by reason of its quality of increasing the weight of silk. The author finds that clean, raw silk has a very definite affinity for both strongly and weakly oxidised Logwood extracts and the silk undergoes a marked increase in weight. At the same time a considerable increase in volume and a less marked decrease in length of the fibre is observed. The increase in weight of the silk depends on its condition and previous treatment, on the degree of oxidation of the Logwood, on the composition of the bath and on other factors. Silk treated with tannin materials has less affinity for Logwood than untreated silk, but Hamatin and Hamatoxylin are absorbed equally well by both kinds. The greatest absorption of silk is attained when it is loaded with tin phosphate: in this condition it can take up more than its own weight of Logwood.—J. C. C.

Dye solutions and inorganic substances: Reactions between — W. P. Dreaper and W. A. Davis. Seventh Int. Congr. Appl. Chem., London, 1909.

THE dye solutions (1 in 10,000) were slowly passed through a 5-inch column of purified and ignited sand, and the volume or weight of colourless liquid passing through noted. The end reaction, when the dye commenced to pass as well, was sharply defined. With sand of standard quality and using a solution of Night Blue, the ratio, weight of dye retained: weight of sand employed, = 0.000147. Two other results gave 0.000148 and 0.000148. With sand of a larger grain the figures were 0.000084 and 0.000076. With Cotton Red 4B, there was practically no "dyeing" action, the figure obtained being 0.000036. Primuline showed a similar result, viz., 0.00004. Thus the "direct" dyes were not absorbed so much as the Night Blue (basic). Anthracene Red 3B (acid) gave a figure of 0.000041. Picric acid gave no "dyeing" action whatever. The effect of the addition of sodium chloride to the solution of the dye was marked in some cases. With Night Blue the dye retained was in the ratio of 1.39 to 2.41 with a solution containing 4 grms. of salt per litre. With a solution containing 10 grms. per litre, the desolution of the dye was complete enough for the whole of the dye to be retained in the upper part of the column of sand, until the passage of the solution was entirely stopped. In this way actual de-solution of the dye was immediately recognised, the lower portion of the sand column remaining colourless. In some cases this was not complete, as with Anthracene Red 3B, where both reactions were noticed. With picric acid and 1 per cent. salt solution there was no dyeing action. With Primuline and Cotton Red 4B, there was no de-solution with a 1 per cent. solution of salt, but the dyeing was increased five-fold.

Charcoal: Decolorising action of various forms of — E. Knecht. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author has already shown (see this J., 1907, 949) that by decreasing the percentage of nitrogen in an animal charcoal, its affinity for acid dyestuffs like Crystal Scarlet is proportionately diminished. In continuation of this work, he now shows that by decreasing the percentage of nitrogen, the affinity of the charcoal for a basic colour like Methylene Blue is not materially altered. If, on the other hand, purified animal charcoal be heated with aluminium powder or zinc dust, and then treated successively with hydrochloric and hydrofluoric acids to remove impurities, its affinity for Methylene Blue is greatly diminished. The affinity for Crystal Scarlet is also diminished by this treatment (probably owing to unavoidable loss of nitrogen), but not in proportion to the decrease in the affinity for Methylene Blue. The opinion expressed by Paterson and by Glassner and Suida that animal charcoal owes its decolorising action to the presence of organic compounds which are stable at a red heat, is upheld by the author. The decolorising action of other forms of charcoal, such as cocoa-nut charcoal, lamp-black, acetylene black, and naphthalene black, is also discussed, and it is shown that the more closely the substance approaches in composition to pure carbon, the less is its decolorising power. It is highly probable that absolutely pure amorphous carbon, however fine its state of division, would be found to be devoid of any decolorising power on either acid or basic dyestuffs. The absorption of iodine from its solution in potassium iodide by animal charcoal was found to depend, like that of Crystal Scarlet, on the amount of fixed nitrogen contained in the charcoal. The absorption of colouring matters by animal charcoal cannot therefore be adduced as evidence that dyeing is a mechanical process. The fact that, under similar conditions, animal charcoal takes up acid colours belonging to a homologous series in the proportion of their molecular weights, shows that here also chemical action is at work.

Aniline Black: Chemical technology of — A. G. Green. Seventh Int. Congr. Appl. Chem., London, 1909. (See also J. Soc. Dyers & Col., 1909, 125, 188—194.)

AFTER a description of the chief methods at present in use for the production of Aniline Black on the fibre,

the author proceeds to a discussion of its constitutional formula.

The oxidation of aniline occurs in the following stages:—

1. Emeraldine. 2. Nigraniline. 3. Ungreenable Black.

These products are contained in variable proportion in commercial Aniline Blacks. Whilst Nigraniline is readily reconverted into Emeraldine by reduction with sulphurous acid, Ungreenable Black is stable to sulphurous acid and only reduced by hydrosulphites giving a leuco-compound from which the black is regenerated by air oxidation. The "greening" of ordinary Aniline Black by acids is explained by the observation that Nigraniline is converted by acids into Emeraldine, the reduction being effected by the simultaneous oxidation of another portion of the Nigraniline into quinone. The author assigns to Emeraldine the structure:—

deducing this formula from its behaviour on oxidation and reduction (Nietzki, Liechi and Suida), the analysis of its hydrochloride (Nietzki), and its stability to acids. The base recently described by Willstätter and Moore under the name of "Emeraldine," to which they assigned the constitution:

is almost certainly not identical with true Emeraldine. It differs from the latter in its greater solubility in solvents, its instability to acids, and the colour of its solution in concentrated sulphuric acid, which is crimson instead of violet.

Whilst Nigraniline is derived from Emeraldine by the removal of hydrogen and can be readily reconverted into Emeraldine on reduction, the Ungreenable Black is probably not a product of further oxidation, but a condensation product with aniline. The author assigns the following formulae to these compounds:—

The latter compound is therefore a phenyl-phenazonium salt and bears to Nigraniline the same relationship as Safranine does to the Blue Indamine. This view is substantiated by the fact that the aniline in the condensation with Emeraldine or Nigraniline may be replaced by any primary amine even if para-substituted (for instance, paratoluidine), but not by a tertiary amine such as dimethylaniline. The analyses of Willstätter and Moore for their so-called "Polymerisation Black" also agree with this structure.

In order to obviate the weakening of the fibre which invariably results from the employment of chlorates in "aged" Aniline Blacks, the author has endeavoured to replace this oxidising agent by atmospheric oxygen. This has been successfully effected by making use of the observation that a small quantity of a paradiamine (e.g., para-phenylenediamine) constitutes, when associated with a copper salt, a catalytic system by means of which aniline can be readily oxidised by air alone into Emeraldine and even into Ungreenable Black (Eng. Pat. No. 16,189 of 1907). (See also this J., 1908, 683.)

The first stage of the reaction is undoubtedly the formation of the Blue Indamine: $\text{NH} : \text{C}_6\text{H}_4 : \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2$, which then undergoes further condensations with aniline giving complex indamines, from which the Emeraldine is formed by splitting off the paradiamine. The latter is thus regenerated and able to enter into reaction with fresh quantities of aniline.

Steaming of fabrics. A. Scheurer. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author has investigated the quantity of air remaining in various types of steaming apparatus. Special attention was paid to the Mather-Platt machine which gives a steaming of two minutes' duration. Air in any such apparatus seriously interferes with the action of reducing agents, such as the hydrosulphites, which are

largely employed in printing. Its presence also causes a fall in temperature inside the machine. If the temperature in a continuous Mather-Platt steamer be less than 100° C., the atmosphere is saturated if the steam plate which forms the ceiling of the apparatus is maintained at about the same temperature as the interior of the machine.—P. F. C.

Chemistry of vegetable fibres. Schwalbe. See XIX.

PATENTS.

Cotton waste, &c.; Extraction of oily and greasy matter from —. G. Putnam, Hemel Hempstead, and F. Dunn, Boxmoor. Eng. Pat. 12,312, June 6, 1908.

THE volatile solvent is introduced at the bottom of the chamber into which the waste is placed, and passing upwards through the material overflows into another chamber from which it is distilled and recovered. The chambers are fitted with perforated steam pipes which permit of a rapid vapourisation of the solvent.—F. M.

Silk and spun silk; Process for increasing the elasticity and strength of weighted —. Deutsche Diamant-Ges.m.b.H. Ger. Pat. 210,341, April 18, 1907.

THE process consists in treating the silk in the hank form with enzymic or non-enzymic malt preparations, or with preparations containing maltose. For example, the silk after being dyed, brightened, and dried in the usual manner, is treated for about 1 hour in a bath containing 60 per cent. (on the weight of the silk) of diastase. It is stated that by this treatment the handle, lustre, elasticity, and strength of the silk are all improved.—A. S.

Black upon textile fibres; Production of —. The Calico Printers' Association, Ltd., and E. A. Fourneaux, Manchester. Eng. Pat. 7345, Oct. 2, 1908.

ANILINE or homologous bases are oxidised in the presence of either strong or weak acids and *p*-phenylenediamine by the joint action of a suitable metallic chlorate and a catalytic agent, preferably a vanadium salt. An addition to the liquor of a mineral salt with an acid function, such as aluminium chloride, is beneficial. Example: Two parts of commercial *p*-phenylenediamine are dissolved in 5 parts of hydrochloric acid (23° Tw.) and 30 parts of water. Into this mixture 10 parts of aniline oil are stirred. A solution of 10 parts of formic acid (90 per cent.) in 15 parts of water is next added, then a solution of 7 parts of sodium chlorate in 10 parts of water, and finally 10 parts of a solution of aluminium chloride (45° Tw.). The mixture thus obtained is suitably diluted with water to which has been added enough vanadium chloride solution to correspond to one part of ammonium vanadate in 200 parts of the padding solution. The resulting liquor is applied to the fabric which is then dried and either aged or steamed, and if necessary is finally chromed. It is claimed that by this process, the weakening of the fibre due to the formation of oxycellulose is largely avoided.—P. F. C.

Dyeing, bleaching and treating fibrous materials; Apparatus for —. T. Halliwell and Mather and Platt, Ltd., Manchester. Eng. Pat. 7671, Oct. 7, 1908. Addition to Eng. Pat. 14,780, June 27, 1907 (this J., 1908, 853).

THE modification of the apparatus described in the original patent permits of material being treated in the loose state, or as yarn in hanks, cheeses, etc., or in the piece. Loose material, or yarn, is packed into the annular space between the perforated walls of an outer and an inner cylinder. The base of this hollow drum is solid and is fitted centrally with a tubulure which fits into a hole in the bottom of the dye-vat; the material is pressed down and kept in position by a cover which fits into the drum. Pieces are rolled, between flanges, on to a perforated cylinder the projecting end of which fits into the hole in the bottom of the dye-vessel.—F. M.

Sulphide colours; Method of treating dyeings with —. R. B. Rausford, London. From L. Cassella und Co., Frankfurt a/M., Germany. Eng. Pat. 17,267, Aug. 17, 1908.

It is found that the fastness of the dyeings produced with sulphide dyestuffs is much improved by an after-treatment

with nickel salts. After-treatment with copper salts could not be carried out in iron vessels, but with nickel salts there is no such drawback. The material, after dyeing, is treated in a hot, fresh bath with 2–3 per cent. of nickel sulphate (or with 1–1½ per cent. of nickel sulphate and 1–1½ per cent. of potassium bichromate) and about 5 per cent. of acetic acid. F. M.

Viscose threads or artificial silk: Apparatus for producing and treating — A. Delubac, La Bégude, Assignor to Soc. Franç. de la Viscose, Paris. U.S. Pat. 923,777, June 1, 1909.

SEE Fr. Pat. 377,424 of 1906; this J., 1907, 1087.—T. F. B.

Emulsions for use in washing raw wool and for other purposes, Crefelder Seifenfabr. Stockhausen und Traiser, Crefeld, Germany. Eng. Pat. 21,289, Oct. 8, 1908. Under Int. Conv., Oct. 8, 1907.

SEE Fr. Pat. 396,493 of 1908; this J., 1909, 612.—T. F. B.

Fibrous materials: Apparatus for treating — with liquids. H. Thies, Crefeld, and W. Mathesius, Berlin. U.S. Pat. 923,310, June 1, 1909.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Alkali, &c., works: Forty-fifth annual report on — by the Chief Inspector. Proceedings during the year 1908, &c. March 18, 1909, 135. Price 61d.

THE total number of works registered in the United Kingdom on Dec. 31, 1908, was 1424, an increase of 35 as compared with 1907; this includes 163 works in Scotland. The number of registered alkali works is 81, of which 9 are in Scotland. The total number of separate processes of manufacture under inspection is now 1839, as compared with 1821 for 1907. There is a noticeable increase in the number of works manufacturing sulphate and chloride of ammonium, these, with gas liquor works, accounting for over 31 per cent. of the processes under inspection.

There have been 5 prosecutions under the Alkali Act during the year, all of which were pending at the close of 1907, penalties ranging from £2 to £50 and costs being inflicted. In 3 other cases back fees have been accepted in lieu of penalties incurred for non-registration.

There has been considerable depression in the alkali and wet copper industries throughout the year. 419,693 tons of burnt cupreous pyrites were treated in 1907 by the wet copper process in England and Scotland, the estimated produce of valuable metals being 15,105 tons of copper, 1927 oz. of gold, and 335,683 oz. of silver; the corresponding figures in 1906 being 400,055 tons of burnt ore, 14,401 tons of copper, 1837 oz. of gold, and 320,045 oz. of silver.

Owing to depression, plant has not been fully employed, as a whole, in the alkali waste works. Large scale experiments have been tried and justify extended use of the new contact substance, bauxite, to replace the oxide of iron filling in the Claus kilns, the loss of sulphur as sulphur dioxide being materially reduced.

The imports of pyrites in 1907 were 769,141 tons, about 70 per cent. coming from Spain, the output in the United Kingdom amounting to 10,194 tons. It is estimated that the consumption of pyrites for the manufacture of sulphuric acid alone must exceed 600,000 tons per annum. In three works zinc blende is used as a source of sulphur. The difficulties surrounding the

manufacture of sulphuric acid by catalytic processes are considered to have acted as a deterrent to their extensive use; the number of works requiring acid of the very highest strength that these processes supply is very limited. The advantage of the use of such acid in the manufacture of high strength explosives has, however, led to some increase in demand, and in the colour industry also, increasing demand may be looked for. Experiments have been made in the Widnes District to reduce the white fume so characteristic of sulphuric acid concentrating plant, where high temperature is employed, and it is found that the fume and acidity are greatly reduced by treatment with hot water, but it is noted that the white fume does not indicate unduly high acidity of the chimneys. In District No. 4 (North and East Lancs.) it is reported that the bottom inlet to chambers is being adopted more extensively and at fresh works, and the use of nitric acid in place of nitre is still finding favour, there being no tendency to revert to "potting." The total chamber capacity in this district is slightly less than 6,114,738 cb. ft., the figure for the previous year. The decrease, however, is due to the increased amount of acid made in a given space, 12 and 15 cb. ft. of chamber space per lb. of sulphur burnt being quite common, and 20, 30, and 40 cb. ft. almost a thing of the past. In District No. 6 (South and South-West of England) the use of fans for the purpose of draught on the sulphuric acid plants is said to be extending and is found to have a steady effect on the chamber working. "Fused silica" vessels in place of porcelain ones at works for rectifying sulphuric acid are again reported to have given satisfaction. The Petersen "regulator tower" system (this J., 1907, 870; 1909, 520), after a trial of some months at one works, where tower plant not specially designed for the purpose was utilised, has been found unsatisfactory and given up.

Progress is reported in attempts to improve the method of working at tinplate flux works, an industry which is almost confined to S. Wales and Monmouthshire and the Forest of Dean. As noticed in last year's Report (this J., 1908, 804), considerable losses of tin occur, owing to the oxide being mechanically carried along with the furnace gases. Where the flux-skimmings, which contain large quantities of volatile chlorides, are kept separate from the scruff, the latter alone being furnace, a cleaner tin is obtained from the scruff and the scruff house is free from fume, the scruff also being worked off in two-thirds of the time. It is considered that "the best practical means" for preventing the discharge of noxious gases to the atmosphere and for rendering such gases, where discharged, harmless and inoffensive should include:—(1). Separation of the flux-skimmings from the scruff proper. (2). Depositing flues of length and sectional area adequate for the scale of operations, as conducted. (3). A chimney of adequate height, by which the gases are ultimately discharged. (4). Probably also the provision of a final wash tower. The flux-skimmings are completely disintegrated by continued treatment with hot water.

The total quantity of white salt produced from brine, and salt contained in brine used for making alkali by the ammonia soda process, was, in 1907, 1,738,636 tons, the figure for 1906 being 1,734,593 tons.

There appears to be a marked increase in the quantity of mineral phosphate imported, as compared with 1906. The amounts, in tons, of manure materials imported in 1906, 1907, and 1908 were:—

	1908.	1907.	1906.
Guanos	34,417	31,278	24,906
Mineral phosphates	530,177	504,528	442,970
Sodium nitrate (including that used for the manufacture of acids)	145,724	113,894	108,486

The exports of ammonium sulphate in 1908 amounted to 235,000 tons, as compared with an estimated home consumption (for all purposes) of 83,000 tons. The figures in 1907 were 230,000 and 87,500 respectively.

The number of sulphate and chloride of ammonium works and gas liquor works has risen from 554 in 1907 to 578 in 1908. Where purification by oxide of iron is the method used, an increasing number of works have adopted the form of oxide heap (this J., 1906, 882) in place of the box purifier constructed of brick and cement; in either case an impervious bottom must be prepared, and the arrangements for distribution of the noxious gases among the purifying heap or heaps requires observance of the same precautions as if box purifiers were used. It is insisted upon, that during emptying and recharging, a purifier should, for safety of the workmen engaged, be isolated by valves of the hydraulic type and not by inefficient screw-down valves.

In view of the importance of the exact determination of chloride in gas liquor, the method of determining chloride in the presence of thiocyanate, devised by Resanoff and Hill (this J., 1907, 1197), has been carefully tested. It is found that the use of nitric acid as an oxidising agent to decompose thiocyanate and thio-sulphate requires more time than a mixture of hydrogen peroxide and potassium chromate, and is, moreover, inadmissible in the case of gas liquors, since oxidation is always incomplete. The peroxide method, which is recommended as having given accurate results with liquors from every source of supply, is carried out as follows:—The gas liquor, freed from sulphide and cyanide by boiling, and from any ferrocyanide by precipitation with iron alum, is diluted to 150 c.c., 25–50 c.c. of hydrogen peroxide (10 vols., "free from chloride") are added, the liquid is boiled for 15 minutes, 6 drops of a 10 per cent. solution of potassium chromate are added, and the boiling continued for 2 minutes; a slight excess of sodium carbonate is then added and the solution again boiled for 1 minute, filtered, cooled, and made up to 250 c.c.; an aliquot part is titrated with $N/10$ silver nitrate, after being made neutral with dilute nitric acid, a blank experiment being conducted with 10 c.c. of $N/10$ sodium chloride and the same volumes of water, hydrogen peroxide, and chromate solution, to determine the correction for traces of chloride in the reagents used. A memorandum is also inserted by S. E. Linder to the effect, that ammonium thiocyanate is found to be quite stable in aqueous solution, when pure, the substance suffering no decomposition on boiling the solution.

*Amount of ammonia produced in the United Kingdom
(expressed as tons of ammonium sulphate.)*

	1908.	1907.	1906.
Gas works	165,218	165,474	157,160
Iron works	18,131	21,024	21,284
Shale works	53,628	51,338	48,534
Coke oven works	64,227	53,572	43,677
Producer-gas and carbonising works (bone and coal) ...	24,024	21,873	18,736
	325,228	313,281	289,391

The increase in activity in Cornwall, noted in last year's Report, in the mining of ores containing arsenic, has received some check during 1908, but the output of white arsenic from Cornwall and Devon in 1908 amounted to 1919 tons, as compared with 1473 tons in 1907.

The chemical works in the North of England are reported to have been less busy than in former years owing to the general depression of trade. In the eastern and south-eastern counties, a distinct depression is also reported among all classes of chemical manufactures in the past year. The depression in the cement industry continues, two works having been removed from the register and others having produced no cement. The workable kiln plant in the South-Eastern District at the close of 1908 was as follows:—82 open kilns (mostly idle); 1054 chamber kilns (many of which have also remained idle); 35 Schneider kilns; and 62 rotary cylinder kilns.

A study has been made of the interaction of methane and ammonia at comparatively low temperatures, in the presence of a neutral substance as catalyst, with a

view specially to ascertaining the mechanism of formation of hydrocyanic acid, in the course of coal carbonising. Coal-gas, deprived of its illuminants, was used in the place of pure methane. In the presence of porcelain, methane itself decomposes above 800° C., with the deposition of carbon, as observed by Bone (this J., 1908, 887). Wood charcoal has a similar thermal effect below 750° C., the effect rapidly increasing with rise of temperature. With moist coal-gas, in the presence of wood charcoal, an oxidising effect is to be noticed, besides the thermal effect, carbon monoxide being mainly produced; this has an important bearing on the economy of carbonisation, when steam is admitted, as in the Dessau intermittent vertical retort, towards the close of the carbonisation process. Ammonia is produced at all temperatures between 720° and 935° C. by the passage of coal-gas over wood charcoal, its formation being favoured by high temperature and a slow rate of flow. Hydrocyanic acid is stable at 935° C., in the presence of wood charcoal and moist coal gas, and traces are, moreover, formed at this temperature, probably as a secondary product by the interaction of ammonia and carbon, since its formation is also favoured, like that of ammonia, by a high temperature and slow rate of flow. In gas works and coke ovens, therefore, as observed by Bone (*loc. cit.*), temperature is by no means the only factor of importance, but the amount of contact surface, in proportion to the rate of gas evolution, has also to be considered, having a great influence on the products obtained. With a mixture of methane and ammonia, the critical temperature for the formation of hydrocyanic acid, in the presence of wood charcoal lies between 755° and 805° C. At 805° C. the yield of hydrocyanic acid is only slightly affected by the rate of flow, but above 900° C. increasing rate of flow gives a much larger production. The reduced yield at the slower rate is attributed to the rapid dissociation of ammonia into its elements, since hydrocyanic acid, once produced, is stable at such temperatures. The maximum yield of hydrocyanic acid was obtained at 855° C., 19.7 per cent. of the ammonia used being transformed into this substance. In the light of these results, the working of the continuous vertical retort (Woodhall-Duckham) is considered. A zone of maximum and continuous heat exists perhaps at about three-fifths of the depth of the retort, measuring from above. Here the horizontal section will be well filled, under normal conditions, with incandescent solid, with absence of any central gas channel, such as characterises the horizontal section of an intermittent vertical retort. Here also the gas pressure will be at a maximum, while the rate of flow of gas, from its diminishing evolution, will be much lessened, as compared with higher zones in the retort. These conditions all favour decomposition of methane and any accompanying ammonia and the formation of hydrocyanic acid from its elements. The analyses of gas liquor from the continuous vertical retort show an increased ratio of hydrocyanic acid to ammonia, as compared with that from a horizontal retort; the tar presents generally the characters associated with low temperature carbonisation, being low in naphthalene. Analyses of ammoniacal liquors from coal partially carbonised at very low temperatures (427°–454° C.) are also given, in all of which, however, cyanogen compounds are present, although the critical temperature for the formation of cyanogen from carbon and ammonia is above 750° C., as already stated.

In Scotland the number of works registered, as compared with the preceding year, has increased by 5. The quantity of pyrites burnt for the manufacture of sulphuric acid was 9500 tons less than in 1907. Fan draught is being extended here in connection with the chambers, and the use of water sprays in place of steam jets, as mentioned in the Report for last year, has been found satisfactory. A plant for the recovery of nitric acid from nitrous fumes has continued in successful operation. Spontaneous firing of the contents of a purifier, containing a mixture of 2 parts of lime and 1 part of oxide of iron is said to have occurred at a tar works, and the use of lime alone has been reverted to. The average number of furnaces in blast at iron works, which in 1906 and 1907 was 90.35 and 90.44 respectively, fell in 1908 to 75.95.

The total shale mined in the United Kingdom during 1908 was 2,891,564 tons, and the yield, in lb. of sulphate of ammonium per ton of shale mined, 41.5, the corresponding numbers for the preceding year being 2,675,989 and 43.0. The means taken to prevent the escape of noxious and offensive gases in paraffin oil works, in consequence of the Act of 1906 (see last Report), have been effectual, and considerable amounts of valuable products have been conserved, that formerly escaped to vitiate the atmosphere.

—F. SONS.

Nitrosyl perchlorate: the mixed anhydride of nitrous and perchloric acids. K. A. Hofmann and A. Zedtwitz. Ber., 1909, 42, 2031—2034.

On adding nitric acid which had been coloured reddish-yellow by exposure to light, to the hydrate of perchloric acid, $\text{HClO}_4 \cdot \text{H}_2\text{O}$, colourless crystals of the anhydride of nitrous and perchloric acids were produced. This was obtained in better yield by leading nitrous acid gas into perchloric acid. Pure commercial perchloric acid (about 30 per cent. strength), was evaporated until it attained a temperature of 110°C . and dense white vapours were evolved. After cooling to the ordinary temperature or to 0°C ., the mixture of nitric oxide and nitrogen peroxide produced by the action of nitric acid on sodium nitrite, was led into the perchloric acid, whereupon colourless doubly-refractive leaflets of the new anhydride separated. By removing the crystals, concentrating, cooling, and again leading in nitrous vapours, and repeating these operations, nearly the whole of the perchloric acid was converted. The crystals were left on a porous tile for some hours over phosphorus pentoxide in an atmosphere of nitrous vapours, and then dried *in vacuo*. The nitrosyl perchlorate thus obtained has

the composition, $\text{ClO}_3\text{NO} \cdot \text{H}_2\text{O}$; the molecule of water can be almost completely removed by drying *in vacuo* over phosphorus pentoxide, without sensibly altering the properties of the compound. The anhydride can be kept for several days in a perfectly dry atmosphere without any evolution of nitric oxide; at 108°C . brownish-yellow nitrous fumes are developed, and at a considerably higher temperature, the white residue volatilises without melting. It is only slightly hygroscopic. When treated with a few drops of water, the greenish-blue colour of nitrogen trioxide is produced and brown nitrous fumes are evolved. Nitrosyl perchlorate converts methyl alcohol immediately into methyl nitrite; ethyl alcohol and acetone become ignited and cause slight explosions. Glacial acetic acid has no action at first, but causes evolution of nitrous fumes on warming. With dry ether there is evolution of gas followed by an explosion. With primary amines of the benzene series violent reactions are produced; e.g., with aniline a dangerous explosion may take place. Reactions are also produced with urea, pinene, phenols, pyridine, and chloroform.—A. S.

Ammonia: Electrolytic oxidation of —. A. Brochet and G. Boiteau. Bull. Soc. Chim., 1909, 5, 667—675.

AMMONIACAL solutions of ammonium carbonate or nitrate were electrolysed under varying conditions of temperature and current density, and the yields of ammonium nitrate compared. This yield increases with the current-density,

but there is also a considerable rise in the tension at the terminals and in the temperature. The yield decreases rapidly when the proportion of nitrate is raised. The electrolyses were carried out between electrodes of carbon, platinum, or iron. On electrolysing a dilute solution of ammonia alone between carbon electrodes, a poor yield of nitrate was obtained, but small amounts of carbonate and carbon dioxide were formed, the anode showing a considerable loss in weight. Taking as electrolyte a solution of the carbonate in dilute ammonia (1:1), better results were obtained. The results with electrodes of platinum were very similar. It is noteworthy in this case that while the electrolysis of a solution of ammonium carbonate gives, at the anode, oxygen free from nitrogen, the reverse is the case in the presence of free ammonia, the product consisting of nitrogen free from oxygen. Using electrodes of iron, under ordinary conditions, it was found that no nitrate at all was formed, but that, on the contrary, there was a considerable reduction of that salt by the iron cathode. In the presence of ammonium bichromate, however, the operation went forward as in the case of platinum and a substantial yield of nitrate was obtained.—C. A. W.

Boric acid: Determination of —. R. Mandelbaum. Z. anorg. Chem., 1909, 62, 364—369.

To separate and determine boric acid in borates, the author has modified the method of distillation with methyl alcohol, by conducting the distillation in a stream of air or other indifferent gas, and by receiving the boric acid directly in excess of standard alkali, from which before titration the accompanying methyl alcohol is removed. The apparatus is shown in the accompanying figure.

Air from a gas holder is freed from carbon dioxide and moisture by the two potash wash bottles and the soda-lime tower on the right of the diagram, and passes through the tube, *a*, ending in a capillary opening, to the bottom of the flask, *A* (300 c.c.), which also carries a 100 c.c. stoppered funnel; thence it passes by the tube, *b*, 6 mm. wide and with a capillary ending, into the round-bottomed flask, *B* (150 c.c., neck 20 cm. long and 3 cm. wide), which carries a 25 c.c. stoppered funnel. The flasks, *C* and *D*, hold each 500 c.c. To carry out a determination the weighed substance (0.4—0.7 gm. of borax, for example) is introduced into *B*, and enough 40 per cent. phosphoric acid added to produce monometallic, soluble phosphate—say 4 c.c. to 0.7—0.8 gm. of borax; the whole is gently warmed, avoiding any possible volatilisation of boric acid, till solution is complete. The apparatus is now put together, and all carbon dioxide expelled by a stream of air. A known volume, in excess, of $N/10$ sodium hydroxide is now put into *C*, which is then replaced, and all corks made tight with collodion. The cock, *c*, is closed, and anhydrous methyl alcohol introduced through the funnels. For 0.2 gm. of boric anhydride 150—170 c.c. of alcohol are needed, four-fifths of which are put into *A* and the rest into *B*. The cock, *c*, is opened, and the air regulated so that 2 or 3 bubbles per second enter *C* from the 6 mm. tube which dips into the alkali; then *A* and *B* are cautiously heated, not above 80°C ., and carefully avoiding frothing. In this way 200 c.c. of alcohol can be distilled over in 1—1½ hours; and the distillation of the alcohol from *C* can be proceeded with before all has distilled over from *A* and *B*. When practically all the alcohol has been expelled from *C* (the air-current having been kept up all the time), *C* is rapidly cooled, a little phenolphthalein, and glycerin equal in volume to half the contents of the flask are added, and the excess of alkali is titrated with $N/10$ sulphuric acid. The residue in *B* is tested by Lenher and Wells' method (this J., 1899, 608), to see that no boric acid remains in it. A determination can be carried out in 2—3 hours, and the

results are very accurate. Every care must however be taken to avoid carbon dioxide and to have anhydrous methyl alcohol.—J. T. D.

Calcium; Some double sulphates of —. M. Barre. *Compt. rend.*, 1909, **148**, 1604—1606.

It was found that the solubility of calcium sulphate in water was considerably increased by the presence of ammonium sulphate, and that a double salt having the formula, $\text{CaSO}_4 \cdot (\text{NH}_4)_2\text{SO}_4 \cdot \text{H}_2\text{O}$, was formed, which was stable between 0° and 100° C. in the presence of excess of ammonium sulphate. The concentration of the latter should be 35 per cent. In the presence of an excess of calcium sulphate at 80° C., another double salt was formed corresponding with the formula, $2\text{CaSO}_4 \cdot (\text{NH}_4)_2\text{SO}_4$. In the presence of potassium sulphate, calcium sulphate was less soluble than in pure water, but the double salt, $\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, which was formed, was stable between 0° and 99° C. in the presence of excess of either calcium or potassium sulphate, the double salt $2\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$, described by Ditte, (*Compt. rend.*, 1877, **84**, 86), not being formed within that range of temperature.—O. R.

Chemical reactions in gaseous mixtures under great pressure. E. Briner and A. Wroczynski. *Compt. rend.*, 1909, **148**, 1518—1519.

MIXTURES of gases were subjected to very high pressure by condensing them in thick glass tubes surrounded by liquid air, the tubes were then carefully sealed and allowed to return to a temperature above the critical points of the gases employed. In this way pressures of from 500—1000 atmospheres were attained. Mixtures of nitric oxide and hydrochloric acid react in these circumstances with the formation of nitrosyl monochloride, while nitric oxide and sulphurous acid, hydrochloric and sulphurous acids, nitric oxide and methyl-chloride, and sulphurous acid and oxygen all react to produce compounds which have not yet been identified.—R. L. S.

Aluminium nitride; Preparation of —. A. J. Sofianopoulos. *Bull. Soc. Chim.*, 1909, **5**, 614—616.

WHEN powdered aluminium is heated to redness in a stream of pure dry ammonia, until no more gas is absorbed and the production of hydrogen ceases, a grey, amorphous, spongy mass of pure aluminium nitride, Al_2N_3 , is obtained. In the event of any aluminium remaining unchanged, it may be readily removed by treating the crushed product with warm mercury and then separating the nitride by levigation with water. The nitride is very stable, when dry, and is not attacked by oxygen, even on heating; the halogens, however, readily convert it into the corresponding halide with the liberation of nitrogen, and with acids, caustic alkalis, or boiling water, the nitrogen is split off as ammonia, aluminium hydroxide or a corresponding salt being produced. Hydrazine or hydrazoic acid give the same results as ammonia.—F. Sopex.

Sintering point curve, a simple means of detecting the formation of binary chemical compounds. A. Stock. *Ber.*, 1909, **42**, 2059—2061.

THE formation of a definite compound when a mixture of two substances is fused, is indicated by a maximum

on the melting point curve, but if the compound is dissociated in the fused condition, the maximum is not sharply defined and it is difficult or impossible to deduce from its position the composition of the compound. A simple means of overcoming this difficulty is to plot the sintering point curve, *i.e.*, the curve representing the beginning of the melting; upon this curve the formation of a compound is indicated by a sharply defined apex. In the figure are shown a typical melting point curve (the uppermost one) and two sintering point curves. Of the sintering point curves the lower dotted one represents the temperatures at which small drops are first observed when a small quantity of the mixture is heated in a capillary tube, whilst the other thicker line represents the temperature at which distinct sintering takes place when a larger quantity of the material is heated.—A. S.

Phosphorus-sulphur compounds. IV. Existence of phosphorus disulphide, $\text{PS}_2(\text{P}_2\text{S}_5)$. A. Stock. *Ber.*, 1909, **42**, 2062—2075.

AFter a critical discussion of the literature of phosphorus-sulphur compounds, the author describes various attempts to prepare the so-called phosphorus disulphide, PS_2 or P_2S_6 . In every case, however, the product obtained was the sulphide, P_4S_7 . Also by determining the sintering points (see preceding abstract) of a series of mixtures of the sulphides, P_4S_3 and P_2S_5 , and of various other mixtures of the sulphides, P_4S_3 , P_4S_7 , and P_2S_5 with one another and with sulphur and phosphorus, it was found that at about 300° C. in cases where the composition approached that represented by the formula, PS_2 , the compound actually formed was the sulphide, P_4S_7 . The substances hitherto obtained and described as phosphorus disulphide were evidently mixtures of the sulphides, P_4S_7 and P_2S_5 , which could be separated into their components only with difficulty by the methods employed, *viz.*, distillation and crystallisation. There are only three phosphorus sulphides, the existence of which can be regarded as beyond doubt, *viz.*, P_2S_5 , P_4S_3 , and P_4S_7 . (Compare this *J.*, 1906, 264).—A. S.

Colloidal sulphur; Preparation of —. A. Himmelbauer. *Z. Chem. Ind. Kolloide*, 1909, **4**, 307—308.

IF pieces of pure gelatin are placed in a solution of ammonium polysulphide, they gradually become olive-green in colour, opalescent, and finally white; the ammonium sulphide disappears, and after a few days ammonia only is left in solution. The same results are obtained with agar-agar, but in this case finely-divided sulphur is also precipitated in the liquid. Similar results are obtained if the ammonium polysulphide is replaced by hydrogen sulphide solution. Gelatin rendered slightly opaque in this way showed very small granules at a magnification of 225, and also showed the Tyndall phenomenon, though pure gelatin did not. After two days distinct crystalline growths were visible, mainly spherulites, the gelatin itself being optically clear. A parallel experiment without gelatin showed no separation of sulphur in the same time. A further experiment with gelatin in the dark proceeded in the same way as in the light. Colloidal silicic acid caused no precipitation of sulphur from hydrogen sulphide solution.—E. F.

Bromine production in the United States in 1908. U.S. Geol. Survey, June, 1909. [T.R.]

THE following table gives the production and value of the bromine produced in the United States during the years 1900 to 1908, inclusive:—

	Pounds.	Value.
1900.....	521,444	\$140,790
1901.....	552,043	154,572
1902.....	513,893	128,472
1903.....	598,500	167,580
1904.....	897,100	269,130
1905.....	1,192,758	178,914
1906.....	1,283,250	165,204
1907.....	1,379,496	195,281
1908.....	1,055,636	102,344

The bromine industry in the United States is centred in Michigan, Ohio, Pennsylvania, and West Virginia. The low price at the end of 1907 and at the beginning of 1908, when bromine was sold as low as 10 cents per pound in carload lots, f.o.b. at the works, is believed to be below the cost of production to the bulk of the manufacturers. The trade has been exceedingly poor, and much of the bromine made remains unsold on the hands of the producers.

Salt production in the United States in 1908. U.S. Geol. Survey, June, 1909. [T.R.]

In 1908 the quantity of salt produced in the United States was 28,822,062 barrels of 280 pounds, valued at \$7,553,632; in 1907 the production reported was 29,704,128 barrels, valued at \$7,608,323. Expressed on a tonnage basis these quantities represent an output of 4,158,578 short tons in 1907 and of 4,035,089 short tons in 1908. In 1907 the average net value was 25,614 cents per barrel, or \$1.83 per short ton; and in 1908, 26,208 cents per barrel, or \$1.87 per short ton.

The following table shows the quantity and value of salt reported as produced in the United States from 1900 to 1908:—

	Barrels.	Value.
1901.....	20,506,661	\$6,617,449
1902.....	23,849,231	5,608,636
1903.....	18,908,089	5,286,988
1904.....	22,030,002	6,021,222
1905.....	25,906,122	6,065,922
1906.....	28,172,380	6,658,350
1907.....	29,704,128	7,608,323
1908.....	28,822,062	7,553,632

Sodium nitrate statistics. Shipments, consumption, stocks, and prices, from 1907 to 1909. W. Montgomery and Co., London, June 30, 1909. [T.R.]

Sulphurous acid in the gases of the lead chamber [for the manufacture of sulphuric acid]; Determination of —. F. Raschig. Seventh Int. Congr. Appl. Chem., London, 1909. Z. angew. Chem., 1909, 22, 1182—1185.

THE determination of sulphurous acid in chamber gases by the method commonly employed in testing furnace gases, namely decolorisation of a known volume of N/10 iodine solution in presence of starch, in Reich's apparatus, fails owing to the presence of nitrous acid. If, however, sodium acetate be added to the iodine solution, then the free acid produced is acetic acid, and the nitrous and sulphurous acids form sodium nitrite and sulphite respectively, which salts, as Divers has shown, do not interact. In presence of sodium acetate, then, the sulphurous acid in chamber gases can be determined by means of iodine solution, and if subsequently the free acid be titrated, and the amount due to the acid liberated in the reaction between sulphurous acid and iodine be deducted, the amount of nitrous gases can also be approximately

ascertained, since these are converted into either nitrous acid or nitric acid, which liberate a corresponding quantity of acetic acid. By applying this method to the determination of the sulphurous acid in the gases entering and leaving the Glover tower, it was found that from one-sixth to one-seventh of the total production of sulphuric acid is formed in this tower, the daily production of the tower being 20—30 times greater than that obtained by so-called "intensive" working in lead chambers. The chief factor contributing to the high acid-producing efficiency of the Glover tower, the author considers to be the intimate contact of the cooling agent (the descending acid) with the gases; the importance of this factor was indicated by Lunge in 1889. By producing similar conditions of cooling, using sulphuric acid as cooling agent, throughout the system, the production of acid per unit of reaction space could be considerably increased, but two points must be borne in mind, disregard of which was probably the cause of past failures of attempts in this direction. It is immaterial whether the cooling is effected in the chambers by means of an acid spray or in towers similar to the Glover tower, but the concentration of the cooling acid must be adjusted in accordance with the composition of the gases, and a sufficiently large volume of cooling acid must be employed. For the weaker gases which leave the Glover tower, an acid of lower strength than 50° B. must be used for cooling, otherwise water vapour would be removed from the gases and the latter rendered more or less incapable of interacting; acid of 48° B. is suitable. With regard to the volume of cooling acid if the amount of acid passing down the Glover tower be taken as a guide, then a quantity equal to the amount of acid produced by a given plant in 2—3 weeks must be circulated daily for the cooling of the gases, the warm acid withdrawn from the bottom of the chambers being cooled, diluted to 48° B., and used over again. For a plant producing 15,000 kilos. of acid daily, the necessary amount of cooling acid would be about 250,000 kilos. Beside the saving in chamber space by the adoption of this

proposal, the consumption of nitric acid would also probably be reduced. Nitrous oxide is most likely to form in places where dilute acid is present, that is where small drops of water condense from the water spray now largely employed. With a spray of acid of 48° B. there would be no possibility of weaker acid being anywhere present in the chamber, so that no abnormal formation of nitrous oxide could take place.—A.S.

Atmospheric nitrogen; Utilisation of — particularly for the manufacture of air-salt-petre. A. Bernthsen. Seventh Int. Congress Appl. Chem., London, 1909.

AFTER discussing the need of nitrogen compounds in agriculture and reviewing the methods which have been proposed for the utilisation of atmospheric nitrogen the author gives a description of the process worked by the Badische Anilin und Soda Fabrik (see Fr. Pat. 357,358 of 1905 and additions thereto; this J., 1906, 7, 1053; 1907, 23, 178). The electric furnace used, consist-

essentially of an iron tube provided at one end with an insulated electrode, from which on passing the current, arc springs to the adjacent part of the iron tube. A current of air is passed through and carries the end of the arc with it, so that a column of arc flame is obtained, burning quietly in the axis of the tube and surrounded by the air passing through the tube. In the furnace for large-scale working, the air passes into the tube through a number of holes bored tangentially in the portion surrounding the electrode. The insulated electrode can be cooled with water or air, and is provided with a central hollow space through which passes an iron rod. The arc springs from the iron rod. The gases which leave the tube pass down through a conduit lined with firebrick concentrically surrounding the furnace, thus heating the air supply. The apparatus is very simple and durable. If the heat produced, 30 per cent. is employed for heating water and 40 per cent. for producing steam, whilst 17 per cent. is lost by radiation. The calcium nitrate solutions obtained in a later stage of the process are evaporated solely by means of heat generated in the arc. The gaseous oxides of nitrogen are usually recovered by the so-called "acid" absorption process, the gases being passed through an absorption tower, down which water is trickling. The absorbing liquid is circulated through the tower until nitric acid of 40 per cent. strength is obtained. This weak acid is concentrated to obtain marketable nitric acid or is neutralised with limestone to obtain calcium nitrate, which is sold as "Norwegian saltpetre" or "air-saltpetre." Calcium nitrate either pure or containing lime or calcium nitrite can be used directly as a manure in place of sodium nitrate. Recent experience has indicated the possibility of dispensing with the "acid" absorption process and treating the gaseous directly with milk of lime. The furnace gases may also be used directly for making nitrites (see Fr. Pat. 63,643 of 1906; this J., 1906, 847). It is claimed that the process as a whole possesses not unimportant advantages over the Birkeland-Eyde process (see this J., 1906, 27; 1907, 177, 293). The Norsk Hydro-Elektrisk Ivelstof Aktieselskab, the owners of the latter process, and the Badische Anilin und Soda Fabrik have combined to form two new Norwegian companies, and a large factory is to be established in the interior of Telemarken at the Rjukan, and is expected to start running in about two years' time with about 140,000 h.p. A scheme is also in progress for the erection of a factory to use 50,000 p. in South Bavaria. It is estimated that within a few years, the annual output of "air-saltpetre" will reach 10,000 tons.—A. S.

Water, ammonium chloride, lead chloride; Equilibria in the system —. Y. N. Brönsted. Seventh Int. Congr. Appl. Chem., London, 1909.

WHEN crystalline lead chloride is treated with concentrated solutions of ammonium chloride, the crystals lose their transparency and grow together, forming a porcelain-like mass. The change is noticeable with solutions of ammonium chloride down to about $N/4$ in strength, but this change is due to the formation of a double salt shewn by the fact that when lead chloride is dissolved in a boiling concentrated solution of ammonium chloride about 21 grms.) a substance separates on cooling in the form of transparent prismatic crystals, having the composition, $2PbCl_2 \cdot NH_4Cl$. These crystals are decomposed by water and by solutions of ammonium chloride to 0.4 N , becoming opaque and again forming a porcelain-like mass. If this latter change be due to the formation of lead chloride as a solid phase, there should be a particular strength of ammonium chloride solution, lying between 0.4 N and $N/4$ which will be in equilibrium with lead chloride and with the double salt. This is confirmed experimentally.

Lead chloride and pyridine; Equilibrium in the system —. L. Kahlenberg and W. J. Wittich. Seventh Int. Congr. Appl. Chem., London, 1909.

SOLUBILITY determinations with silver chloride and pyridine between $-57^\circ C.$ and $+110^\circ C.$ show that there are two distinct crystalline compounds of silver chloride and pyridine. The two compounds are represented as:

$AgCl_2 \cdot 2C_5H_5N$ and $AgCl \cdot C_5H_5N$, hitherto unknown. The $AgCl_2 \cdot 2C_5H_5N$ occurs between the temperatures $-56^\circ C.$ and $-22^\circ C.$ It appears in the form of minute crystals which are very unstable at temperatures above $-20^\circ C.$ The $AgCl \cdot C_5H_5N$ occurs between the temperatures $-20^\circ C.$ and $-1^\circ C.$ This salt consists of minute needle-like crystals, which are more stable than $AgCl_2 \cdot 2C_5H_5N$. It is most interesting to note that the solubility of the silver chloride decreases from -1° to $+110^\circ C.$ as the temperature rises.

Determining sulphur by catalytic method. Maderna. See XXIII.

PATENTS.

Sulphuric and other acids; Apparatus [sampling] for use in the manufacture of —. W. Firman and A. Cocksedge, Ipswich. Eng. Pat. 52, Jan. 1, 1909.

A DRIP pan, made of glazed stoneware or other acid-proof material, is provided with a central groove, with which a number of divergent grooved branches communicate. The central groove terminates in a common outlet, which projects a short distance from the pan and is fitted with a flange, to which a special nozzle is bolted. This nozzle is trapped in such a way as always to retain a small quantity of acid, and to form a seal for the gases contained in the chamber, in which the apparatus is fixed. On the under side of the pan is a ring, which fits on a pedestal, the top of the latter being inclined so that the contents of the pan flow towards the outlet.—O. R.

Sulphuric acid; Process of condensing acid vapours in apparatus for the concentration of — to 60° and $66^\circ B.$ P. Vialleix and F. Perrin. Fr. Pat. 397,080, Dec. 4, 1908.

CONDENSATION of the acid vapours arising from the concentration of sulphuric acid to 60° and $66^\circ B.$ is effected by embedding in the mass of coke used for the condensation, one or more serpentine coils of lead or other material, in which cold water or acid circulates, or by systematically moistening the coke, or by a combination of these means. Very efficient condensation is thus effected, and, at the same time, the size of the condensing apparatus may be reduced.—F. SODX.

Sodium bisulphate; Utilisation of — for the manufacture of hydrochloric acid and sodium sulphate, and finally of sodium carbonate. D. F. Courtois. Fr. Pat. 397,537, Dec. 16, 1908.

SODIUM bisulphate, obtained as a by-product in the manufacture of nitric acid, is ground with common salt, in the proportion, 6000 kilos. of bisulphate to 2500 kilos. of salt, and the mixture is heated for 1 or 2 hours in a muffle furnace at 300° – $400^\circ C.$ The hydrochloric acid, thus liberated, is recovered in the usual way, and the sodium sulphate, also produced, is converted into sodium carbonate by the Leblanc process.—F. SODX.

Alkali carbonates; Process of manufacture of —. L. Rivière. First Addition, dated Dec. 5, 1908, to Fr. Pat. 396,448, Nov. 16, 1908 (this J., 1909, 599).

AN apparatus is described for effecting the dissociation by heat of the alkali fluosilicates obtained as indicated in the principal patent. It consists of a furnace containing a crucible, into which is fed the fluosilicate and from the bottom of which the molten alkali fluoride flows into a second crucible at a lower level in the same furnace; the silicon fluoride is led to a condensing tower, in which it is treated with hydrofluoric acid. The Addition also includes a process of separating undecomposed potassium fluoride and the potassium carbonate, obtained by double decomposition of the alkali fluoride with chalk, by precipitating the former with aluminium fluoride, as potassium fluoaluminate, this being subsequently decomposed by means of hot milk of lime to give calcium fluoride (to be used as a source of hydrofluoric acid) and potassium aluminate which is then treated with carbon dioxide, so as to produce potassium carbonate and alumina.—F. SODX.

Alkali hydrosulphites; Manufacture of — P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 11,864, June 1, 1908.

ALKALI hydrosulphite solutions, of higher concentration than heretofore obtained, are produced by mixing zinc dust with an aqueous solution of an alkali (caustic soda, ammonia, etc.), or of the salt of an alkali metal with a weaker acid than sulphurous acid (sodium carbonate, etc.), or of sodium sulphite, and then introducing sulphurous acid into this mixture in the proportion of 3 mols. of the acid to 2 mols. of alkali hydroxide or the equivalent quantity of the alkali salts, or in the proportion of 2 mols. of sulphurous acid to 1 mol. of sodium sulphite or its equivalents. For example, 145 parts by weight of caustic soda lye (25 per cent. of sodium hydroxide) are mixed with 200 parts of water, 40 parts of zinc dust are added, and sulphur dioxide is introduced, until the weight has increased by 96 parts, the mixture being cooled meanwhile; the product is left for some hours with occasional stirring, and then milk of lime (40 parts of quicklime to 120 parts of water) is added and the mixture again stirred and allowed to stand for some hours; after filtration, a concentrated solution of sodium hydrosulphite is obtained.—F. SODX.

Alkaline salts; Extraction of — from blast-furnace tar. G. Craig, Glasgow. Eng. Pat. 10,690, Aug. 8, 1908.

THE object of the invention is to recover the potassium salts from blast-furnace tars, in a state of comparative purity for agricultural and other uses. This is effected by washing the tar with acidified water, which may be done without loss of tar. Sulphuric acid is preferably employed, and acidity of the wash water is indicated by its pale yellow tint, a dark reddish colour showing insufficiency of acid. Heat may be applied to keep the tar thin, and in this way the filter-press residues obtained according to Eng. Pat. 2942 of 1907 (this J., 1908, 69) may be successfully dealt with by the process. The aqueous extract is evaporated to dryness and the residue calcined.—F. SODX.

Lixiviating apparatus, particularly adapted for the extraction of sodium nitrate from caliche. W. Hunt, Glasgow. From R. T. Love, Iquique, Chile. Eng. Pat. 1381, Jan. 20, 1909. Addition to Eng. Pat. 7907, March 23, 1906.

IN the apparatus described in the main patent (this J., 1907, 150), the upper end of the downcomer pipe is closed by a cover, and the communication of the circulating gutter with the downcomer pipe is restricted in size, and fitted with a valve, if desired, so that, if the liquid should boil in the pipe, it cannot escape from the upper end with any rapidity. The pressure simultaneously developed in the pipe ensures that the circulation will at once start, or be maintained in the right direction.—O. R.

Sodium aluminate lyes; Process of manufacturing — A. Vergé. Fr. Pat. 397,211, Feb. 17, 1908.

THE process is for the manufacture of sodium aluminate lyes, practically free from soluble silica, and is characterised by the treatment of bauxite, after mere crushing and without preliminary roasting or pulverisation, by a solution of caustic soda in a vessel arranged in such a way, that: (1), the internal temperature (125°–135° C.) corresponds to a pressure of 2.5–3 atmos. in the space above the reacting liquid; (2), a thorough and rapid circulation is maintained throughout the mixture; and (3), the solid particles are kept in constant and violent collision with each other, thus bringing about their disintegration in the liquid. Steam is preferably employed as the means of simultaneously agitating and pulverising the bauxite, but it is found that, to be effective, the pipe leading steam into the vessel must be neither divergent nor convergent, but parallel, and of a diameter depending on the working capacity of the vessel; also, a difference

of about 2.5 atmos. should be maintained between the pressure of the entering steam and its pressure at leaving this latter being 2.5–3 atmos. The apparatus described in Fr. Pat. 380,272 of July 26, 1907 (this J., 1908, 22) arranged to fulfil the above conditions, is particularly suitable for carrying out the process. By way of example it is stated that when 40 litres of mixture are being treated the diameter of the steam pipe should be 3–5 mm., and for a vessel of 4 cb. m. working capacity, 20–30 mm. diameter is necessary. The advantages claimed for this over existing processes are:—(1), a considerable reduction in the cost of plant, power, fuel, wear and tear, and handling; and (2), the possibility of working with cheap silicious bauxites, containing 5–6 per cent. of silica which have hitherto proved useless.—F. SODX.

Zinc sulphide; Process of treating blende for the manufacture of — E. F. Côté and P. R. Pierron. Fr. Pat. 397,631, Feb. 28, 1908.

ZINC blende is melted with iron in an electric furnace and the zinc vapour produced is either treated at once with hydrogen sulphide, in order to convert it into sulphide, or it is first transformed into oxide; the hydrogen sulphide is obtained by decomposition of the iron sulphide formed. The furnace described in previous patent (this J., 1904, 828; 1908, 342, 632, 864) may be conveniently employed, with necessary modifications for treating the zinc vapours. These vapours are made to pass through a supplementary electric furnace filled with glowing charcoal which retains the impurities and reduces any zinc oxide, the zinc vapour being burnt on leaving this furnace and the oxide aspirated to a large depositing chamber. The zinc oxide may be treated with hydrogen sulphide, either in the depositing chamber, or in the apparatus in which the zinc vapour is burnt, or in horizontal rotating cylinders, or in the presence of water with subsequent drying at a low temperature and under reduced pressure. An apparatus is described, which may be used for generating the hydrogen sulphide, consisting of an acid-proof chamber for the reaction between iron sulphide and sulphuric acid, from which the iron sulphate solution gravitates through a series of shallow closed troughs, heated by the passage through them of gases from the furnace below the reaction chamber so as to drive off hydrogen sulphide and promote crystallisation. As a special apparatus for treating the oxide with hydrogen sulphide, twin horizontal iron cylinders are described, which communicate with each other and rotate slowly. These are charged with the oxide and are strongly heated externally, the hydrogen sulphide passing through each successively and the cylinders being discharged alternately; the direction of the heating gas and of the hydrogen sulphide is reversed each time so that the contents of the freshly charged cylinder are treated last.—F. SODX.

Sulphur ores; Furnace for the combustion of — C. Oddo. Fr. Pat. 397,450, Oct. 7, 1908. Under Int. Conv., Oct. 8, 1907.

III.—GLASS, POTTERY, AND ENAMELS.

mic industries: *The use of lead compounds in —.* Mouzin. Seventh Int. Congr. Appl. Chem., London. 09.

so to the dangers attending the use of lead compounds in ceramic industries, the author suggests that the Congress should recommend the Governments to appoint a commission to investigate leadless glazes, in collaboration with manufacturers, and to render aid in these tentative experiments, and also that they should restrain the use of plumbiferous glazes, and allow their use only on condition that the soluble lead portion was converted into thoroughly fritted compounds. The Commission should also examine convenient protective appliances, and pay special attention to the hygiene of ceramic trades.—W. C. H.

rine; *Influence of — in hard-fired glazes.* G. Vogt. Tenth Int. Congr. Appl. Chem., London, 1909. Leichsaal, 1909. 42. 345—346.

WH fluor spar has been a constituent of glazes for a long time, its use is not widely extended. What little literature there is on the subject is contradictory, some authors stating that the fluorine escapes as silicon tetrafluoride during vitrification, whilst others maintain that it remains, either wholly or in part, in the melted mass. Differences of opinion are not surprising, as the composition depends on the atmosphere of the kiln, the temperature and duration of firing, and also on whether the glaze was fired in a crucible or spread out in a layer. The author prepared a glaze made from parts of pegmatite, 1.3 of kaolin, 12.0 of quartz, 11.3 of fluor spar. Pieces were dipped in this, and fired at 1300° C. Analyses of the raw and fired glazes showed that the former contained 4.65 per cent. of fluorine, the latter none. Therefore, if fluor spar be added to a glaze that is required to contain a certain amount of fluorine, it will be necessary to add more silica to counteract the action of silicon tetrafluoride. The absence of fluorine in a fired glaze does not mean that chalk could be substituted for fluor spar. The fluor spar melts at the relatively low temperature of 900°, and dissolves colouring matter, thereby giving better finish and a more brilliant surface to the glaze.—H. H. S.

PATENT.

clay; *Preparation of —.* A. G. Salamon and the Exploration Company, London. Eng. Pat. 13,179, Dec. 20, 1908.

et clay, commercially freed from mica by washing, preferably at a concentration of about 66 to 75

per cent. by weight of water, is conducted into filter-presses of any convenient type. It is there subjected to such a pressure that the cake as it comes from the press contains not more than 30 per cent. of admixed water. By the use of a "washing filter-press," the clay at this stage of the process can be freed from any deleterious colouring matter, and so improved in quality, by treatment with a solution of alum or some such reagent, the excess of the latter being subsequently removed by pure water. The compressed clay is finally dried at a suitable temperature in a furnace, although in some cases it may be found that this treatment is unnecessary.—C. A. W.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Refractory materials; Conductivity, porosity and permeability of —. S. Wologdine. Bull. Soc. d'Encouragement, 1909, 3. 879—942.

THE heat conductivity, porosity (*i.e.*, real and apparent sp. gr.), and permeability to air of a large number of refractory materials were determined, in some cases after different degrees of burning. The most important conclusion advanced by the author is that the heat conductivity of refractory materials depends not only on the quantity of contained air, *i.e.*, on the porosity, as stated by Simonis, but also on the degree of isolation of this contained air, or its mobility, *i.e.*, on the permeability to gases. In general, the higher the temperature of burning, the smaller is the porosity, and the higher the conductivity; but in some cases, as with silica bricks, the percentage porosity remains nearly constant, whatever the degree of burning, although the specific gravity increases, and in these cases the heat conductivity also remains practically constant. To measure the conductivity, the lower surface of slightly conical discs of the refractory materials was heated in a furnace to 400°—1200° C. (generally to roughly 1000° C.); temperatures were determined by thermo-couples, the points of which were placed, one close to the lower surface, a second close to the upper surface, and a third at some distance within the disc; when the temperatures became constant, a water calorimeter was placed on top of the disc, through which a constant quantity of water was passed; the quantity of water passing in a given time, and the amount by which it was heated were determined, as well as the temperatures indicated by the thermo-couples, the lowest one of which was always considerably affected by the introduction of the calorimeter. The curve connecting fall in temperature with thickness of material was found to be a straight line; consequently the actual temperatures of the two faces of the discs were easily determined by extrapolation. Two coefficients of conductivity were calculated: One (A), in small calories, being the quantity of heat transmitted through a thickness of 1 cm. across an area of 1 sq. cm. in 1 second, for a difference in temperature of 1° C.; the second (B), in large calories, being the heat transmitted through a thickness of 1 metre, across an area of 1 sq. m., per hour, for the same difference in temperature of the two faces. The porosity was calculated as usual from the real and apparent specific gravities, and expressed in percentage of total volume. The permeability was determined by measuring the quantity of air forced under constant pressure (of a small height of water column) through a short cylinder of the material tightly enclosed in a glass tube, passage of air between cylinder and tube being prevented by a film of paraffin wax. The results are stated as *c.c.* passing through a thickness of 1 cm. across an area of 1 sq. cm. in one second, under a water pressure of 1 cm. (C); and also in litres passing through a thickness of 1 metre across an area of 1 sq. m. per hour, under the same pressure (D). It was found that the permeability varied in different directions along the same piece of refractory material. Some of the results obtained are summarised in the following table:—

Bituminous road binders; Controlling the consistency of ——. C. N. Forrest. J. Ind. and Eng. Chem., 1909, 1, 378—380.

For determining the consistence of semi-fluid bituminous binders for macadamised roads, the author has elaborated a simple form of viscosimeter, originally suggested by E. C. Wallace. It consists of an aluminium float or saucer and a brass collar (see figure). The brass collar is placed upon an amalgamated brass plate, then filled with the bitumen, which has been softened by gentle heating, and after cooling somewhat, placed in ice water at 41° F. for 15 mins. It is then screwed into the float, and the latter placed on the surface of water heated at 90° F. or any other desired temperature. When the bitumen flows and is displaced by water, the float sinks: the time (in seconds) required is a measure of the consistence of the bitumen. Some of the results obtained with

this (N.Y.T.L.) apparatus are shown in the following table, together with comparative results obtained with the Engler viscosimeter.—

Cement production in Canada, 1908. Engineer, Jun 29, 1909. [T.R.]

According to returns received by the Mines Branch of the Canadian Department of Mines, the total quantity of Portland cement made in Canada in 1908 was 3,490,601 barrels of 350 lb. net, as compared with 2,491,513 barrels in 1907, or an increase of 40.3 per cent. The total quantity of Canadian Portland cement sold in 1908 was 2,662,889 barrels, as compared with 2,436,093 barrels in 1907, an increase of 9.4 per cent. The total consumption of Portland cement in 1908, including Canadian and imported cements, was 3,141,338 barrels of 350 lb. net, as compared with 3,108,723 barrels in 1907, or an increase of 0.9 per cent.

comparisons of production, sales, and imports of Portland cement in 1907 and 1908.

23 plants were distributed as follows:—One in a Scotia using blast furnace slag; 1 in Manitoba using a natural Portland cement; 1 in British Columbia, Alberta, and 3 in Quebec using limestone and clay; 15 in Ontario, of which 12 use marl and 3 limestone. Total daily capacity of the plants using marl was 10,400 cels, as compared with 17,100 barrels per day for all r plants. Of the total quantity of cement made in , 1,573,090 barrels were made from marl, and 1,922,871 ls from limestone and slag.

om the foregoing it will be seen that whereas the ration of cement into Canada has decreased very derably, the manufacture and use of Canadian cement f recent years been steadily increasing.

for road building; Composition and physical pro-
rties of —. E. C. E. Lord. Seventh Int. Congr.
pl. Chem., London, 1909.

DES the regular analytical work a series of
were undertaken to determine the solubility of
furnace products in water and dilute acid and to
the effect of calcium hydroxide and calcium car-
te (limestone) on their cementing values. It was found
the materials in question varied in composition from
id glass to a very basic, wholly crystalline slag rock.
samples were grouped according to silica content
three general types, and the characteristic compounds
ch type are described. The solubility tests indicated
only samples having good cementing qualities and con-
g calcium-aluminium double salts were appreciably
ked by water. The cementing properties have been
ded chiefly to the formation of calcium carbonate and
ted silicates of calcium and aluminium analogous to
secondary compounds found in hardened Portland

cement. By the addition of calcium hydroxide and
calcium carbonate (limestone) these cementing properties
were greatly increased. Certain basic, extremely cemen-
tious, converter slags were found to contain silicate
minerals identical in crystalline form and chemical com-
position with the active elements, alite and belite, of
hydraulic cements. As the result of these investigations,
it was found that by means of simple tests, the solubility,
and hence the cementing values of slags might be readily
determined, and that, by using proper precautions,
excellent materials for road construction could be obtained
from the waste products of converter and blast furnaces.

Mortars: Decomposition of — by sulphate solutions.
M. J. Bied. Seventh Int. Congr. Appl. Chem., London,
1909.

CUBES of mortars (1 : 4 or 1 : 5), even when made with
very fine sand, are soon destroyed when placed in a
saturated solution of calcium sulphate (gypsum), although
they resist the action of 12 per cent. magnesium sulphate
solutions, and of (artificial) sea-water. All mortars
free from alumina are rapidly attacked by calcium
sulphate solutions. Puzzuolanas also are decomposed to
a greater extent by solutions of calcium sulphate than
by those of magnesium sulphate. For four years a
French firm has manufactured a cement, consisting of a
mixture of dehydrated alumina and silicious cement,
which has been successfully employed by French railway
companies in regions containing gypsum.—A. G. L.

Wood; New processes of impregnating —. J. Perten.
Seventh Int. Congr. Appl. Chem., London, 1909.

THE author describes the process of impregnating wood
with salts containing fluorine, which is an advance beyond
previous processes both for efficacy and for cheapness.
He also mentions the attempts that have been made to
utilise the strong fungicidal action of organic dinitro-
compounds, which may be used either alone or in con-
junction with fluorides.—W. C. H.

Alkali, etc., works report. See VII.

PATENTS.

Silica bricks, ganister, and other refractory materials;
Manufacture of —. H. Brearley and F. C. Moor-
wood, Sheffield. Eng. Pats. 14,619, July 10, 1908,
and 7197, Mar. 25, 1909.

THE lime and water added as binding agent to silica
bricks, etc., are replaced by a solution of a calcium salt,
preferably calcium chloride, which, on firing, will yield
free lime evenly distributed throughout the mass. The
calcium salt may in certain cases be made *in situ* from
lime and acid. A part or the whole of the calcium salt
may be replaced by a magnesium salt.—A. G. L.

Terra cotta; Manufacture of architectural —. M.
Barrett and The Leeds Fireclay Co., Ltd., Leeds.
Eng. Pat. 26,284, Dec. 4, 1908.

ARCHITECTURAL terra cotta, without any glaze, but
impermeable and capable of being readily cleaned, is
manufactured, by moulding the block or other article of
ordinary clay or clay mixtures, thoroughly drying the
same, and, whilst hot, spraying on a very thin coating of a
mixture consisting of potash felspar, silica (ground),
ammonium alum, calcium carbonate, china clay, zinc
oxide, potassium alum, and water, to which a colouring
oxide or salt may be added. The composition of the
mixture employed will vary according to the conditions
met with, but, as an example, the above mixture, in the
proportions by weight, 277.5, 32.4, 154.2, 80, 193.5, 60.7,
and 474.7, mixed with cold water to the consistency of
a cream, is suitable for Leeds clay, and produces the best
results when baked at about 1340° C. The surface is
as impermeable as glass and similar to natural stone;
it does not become coated with efflorescence.—F. SONS.

Cement ingredient. W. V. B. Ames, Chicago, Ill. U.S. Pat. 923,238, June 1, 1909.

The cement ingredient consists of phosphoric acid, a metallic compound (e.g., aluminium phosphate), and a fluosilicate.—A. G. L.

X.—METALS AND METALLURGY.

Alloys; Formation of —, by pressure, and reactivity of metals in the solid state. G. Masing. Z. anorg. Chem., 1909, 62, 265—309.

FINE filings of the metals were mixed, and then submitted to pressures up to 5000 atmospheres. The solid rods so obtained were examined micrographically and thermally (heating and cooling curves), and in some cases the electrical conductivity was determined and compared with that of the components. In no case were compounds or mixed crystals produced by pressure; the rods obtained immediately after the operation were found to consist always of fine particles of the individual metals in juxtaposition. These conglomerates therefore resemble in their properties the alloys obtained by fusion and cooling, only where these consist of separated crystals of the individual metals, and differ entirely from them when mixed crystals or compounds separate during the cooling of the fusion. The close juxtaposition of the particles produces, however, in time, changes in the metals even in the solid condition, which are disclosed by the thermal or electrical examination of the pressed blocks. When the metals on fusion can form compounds but no mixed crystals, evidence of the formation of such compounds in the solid pressed block is found, combination doubtless occurring at the surfaces of contact, so that the metals are afterwards everywhere separated by a thin film of the compound; and when the block is heated up to the melting-point of the lowest eutectic formed by the compound and one of the metals, the further formation of the compound goes on with greatly increased rapidity. Similarly, where the metals can form mixed crystals, diffusion of the metals through one another is found to go on in the pressed block, at a rate greatly increased if the temperature be raised; so that by keeping such a block hot, its structure becomes in time identical with that of an ingot of the same ultimate composition cooled from fusion, though the block has been all the while solid. Where in addition to mixed crystals, compounds are formed from the melted alloy, these compounds are also formed in the solid pressed block, much more rapidly than in those cases where only compounds, and no mixed crystals, exist.—J. T. D.

Copper production of the United States in 1908. B. S. Butler. Mineral Resources, 1908. [T.R.]

THE production of copper in the United States in 1908 was 942,570,721 lb. This is the largest production ever made, exceeding that of 1906 by 24,765,039 lb., and that of 1907 by 73,574,230 lb., or 8.4 per cent. The details of production for 1908 are shown in the following table:—

1908.		
	Domestic origin.	Foreign origin.
Electrolytic	656,179,349	218,716,268
Lake	195,503,009	—
Casting	24,166,681	134,726
Total	875,849,129	218,850,994
Total output, domestic refineries	1,094,700,123	

Returns from all smelting and refining companies show that the following stocks of electrolytic, lake, and cast copper were on hand at the beginning and end of the year: January 1, 1908, 125,745,796 lb.; January 1, 1909, 121,876,759 lb.

	1907.	1908.
Total refined output	1,032,516,247	1,094,700,123
Stock beginning of year	40,497,181	125,745,796
Total available supply	1,079,013,428	1,220,445,919
Refined copper exported	465,496,007	*618,613,333
Stock at end of year	125,745,796	121,876,759
Total withdrawn from supply	591,241,803	746,490,000
Apparent consumption	487,771,625	479,955,555

* Exports of pigs, bars, ingots, plates, etc., reported by Bureau of Statistics, less 43,262,285 lb. of blister exported without refining.

Lead production of the United States in 1908. C. Siebenthal. Mineral Resources, June, 1909. [T.R.]

THE following table (in tons of 2000 lb.), showing source of lead smelted or refined in the United States, is based as far as possible on smelter figures. No lead ore from the United States was treated elsewhere during the period covered by the table:—

	1906.	1907.	1908.
Domestic ore	350,153	365,166	310,700
Foreign ore and base bullion	68,546	76,849	97,700
Total from all sources	418,699	442,015	408,400

Production of refined lead.

	1906.	1907.	1908.
Desilverised lead	288,792	284,432	265,500
Soft lead	90,783	99,948	101,000
Desilverised soft lead	20,094	29,800	29,800
Refined primary lead	404,669	414,180	396,400
Antimonial lead	10,546	9,010	13,000

The production of secondary lead was as follows:—

	1907.	1908.
Pig lead	9,990	7,800
Lead in alloys	15,508	10,400
Total recovered lead	25,498	18,200

The domestic exports for 1908 were:—

Type	304
Lead manufactures	\$680,097

Iron, carbon, and phosphorus; Alloys of —. J. T. Stead. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1900, 1019.)

THE article partly bears reference to the work of W. (this J., 1908, 406) and others. In addition, it is stated that the eutectics formed in grey and white pig-iron are practically identical at the moment when solidification begins; but that in white pig-iron the ternary eutectic containing about 2 per cent. of carbon and 7 per cent. of phosphorus, remains as such in the metal during solidification and subsequent cooling, whilst in grey pig-iron this ternary eutectic is changed into a binary eutectic practically free from carbon. This is shown by squeezing the eutectic out of the almost solid metal and analysing, as well as by microscopic examination of the residual grey pig-iron. It is also stated that as the carbon increases in mild steel from 0.1 to 0.5 per cent., the ferrite surrounding the crystals increases in the same proportion, and that the ferrite envelope contains more phosphorus than do the

als first formed. This envelope at first also contains carbon than the interior, but the carbon passes into latter during the subsequent cooling. Rolled steel n carbon, *c.g.*, boiler plate, nearly always contains s of ferrite free from carbon, as well as bands of pear- embedded in ferrite, so-called "ghost-lines." The ntage of phosphorus is higher in the ferrite bands than e pearlite bands, and the bands become more marked increasing content of phosphorus. The formation ese bands cannot be avoided without complete ation of phosphorus.—A. G. L.

illet. *Remarks on the thermal treatment of* —. L. Seventh Int. Congr. Appl. Chem., London, 1909.

CTION is drawn to the influence of the time factor e quenching, annealing and tempering of ordinary special steels. According to the author, this factor often neglected. It is known that, at the temperature enching, the combined carbon (cementite) in the ded steel passes to the state of solution in the iron. explains the increase of hardness observed when s steels of sufficiently high carbon content are heated quenched several times successively. The successive gs which precede each quenching play the same part single but more prolonged heating. This fact is ated by experiments on a manganese-silicon steel. nfluence of time is still greater in the case of special . These can be divided into two classes, since the n elements may exist as double carbides in the itite, or they may be dissolved in the iron. In either t is observed that the solution of the carbide takes with difficulty. It is therefore necessary to increase e duration of heating before quenching, or the reature. However it is always advantageous to the quenching in the neighbourhood of the trans- tion point. The influence of time may be further red in the operation of tempering. Thus it has been a that the same state of temper can be obtained in a y working at different temperatures during variable . The effect will be so much the more accentuated nger the metal is maintained in the neighbourhood e tempering point.—C. A. W.

; *Study of the gases liberated by the action of cupric s on* —. E. Goutal. Seventh Int. Cong. Appl. m., London, 1909.

ction of a slightly acid concentrated solution of the e chloride of copper and potassium at 40° C. on steels a gas containing a small proportion of carbon ide. This carbon monoxide appears to be occluded steel, and its volume varies from one-third to four of that of the steel. (See also this J., 1907, 477.) —A. T. L.

ten-steel; *Analysis of* —. F. W. Hinrichsen. venth Int. Congr. Appl. Chem., 1909, London.

e analysis of tungsten-steels, great difficulty occurs e phosphorus determination, and hitherto literature orded no enlightenment. The following method d to give satisfactory results. The nitric acid on of the tungsten-steel is evaporated to dry- and the residue is fused with sodium peroxide. ubsquent solution in water, together with all ngsten (and chromium), also all the phosphorus overed. From one portion of this solution, ree elements just mentioned, are precipitated itatively by mercurous nitrate, and after ignition, ure of tungstic acid, chromic oxide, and phosphorus ide, is obtained. In another portion of the n, the chromium is determined volumetrically. a third, the phosphoric acid is estimated as follows: r neutralising, and rendering alkaline with ammonia, itation is effected by magnesia-mixture (Jørgensen's d). In this way, very minute quantities of tungstic re precipitated. In order to remove these the sia-mixture precipitate is dissolved off the filter by

the aid of nitric acid, and the phosphoric acid separated by Finkener's method of precipitation in presence of tartaric acid.

Physico-chemical methods; Applications of — to technical problems. [Extraction of silver by Pattio process, and examination of inks.] F. W. Hinrichsen. Seventh Int. Congr. Appl. Chem., London, 1909.

PHYSICO-CHEMICAL methods of investigation were applied to several technical processes, the first being the Pattio-process. In this process, finely divided silver sulphide ores are intimately mixed with a solution of sodium chloride, and then stirred for some time with ferric and copper salts and mercury. According to Kröhnke the reactions which take place are as follows: $2\text{CuCl}_2 + \text{Ag}_2\text{S} = \text{Cu}_2\text{Cl}_2 + 2\text{AgCl} + \text{S}$, and $\text{Cu}_2\text{Cl}_2 + \text{Ag}_2\text{S} = \text{Cu}_2\text{S} + 2\text{AgCl}$. The silver is then reduced by the metals present and forms an amalgam with the mercury. Kröhnke also states that mercury alone can reduce silver from its sulphide. The different equilibria possible in the system: silver sulphide, mercury, sodium chloride, water, were studied by the author. As regards the binary mixtures possible, both mercury and silver sulphide are practically insoluble in water, and neither substance reacts with solid sodium chloride. The equilibria between sodium chloride and water are known. In the remaining mixture of mercury and silver sulphide it was found that a reaction takes place slowly and is apparently only slightly influenced by temperature. With the ternary mixtures possible, it was found that a saturated solution of sodium chloride has no action, either at the ordinary temperature or at 100° C., on mercury or on silver sulphide. By acting on silver sulphide with mercury in the presence of water, it was found that the amount of silver produced was smaller than when no water was present. Probably the effect of the water is mechanical in preventing intimate admixture of mercury and silver sulphide. The system: mercury, silver sulphide, sodium chloride, was not studied, since solid sodium chloride cannot be expected to influence the reaction between mercury and silver sulphide. Investigation of the quaternary system: silver sulphide, mercury, sodium chloride, water, showed that reduction of silver increased with increasing concentration of sodium chloride and with increase in temperature. The yield of metallic silver was also increased if zinc amalgam was employed instead of mercury; the E.M.F. of zinc towards silver sulphide in presence of sodium chloride was found to be nearly 1 volt. Iron shows a much lower tension, and was without favourable influence on the reaction. When sulphuric acid or potassium cyanide solution was substituted for the sodium chloride solution, however, the addition of iron resulted in a greatly increased yield of silver. It was found that with these solutions the mercury remained with an unbroken surface, whilst with sodium chloride solution it broke up into small globules. The favourable action of zinc with this solution is probably due mainly to its diminishing the cohesion of the mercury. The action of iron in presence of potassium cyanide solution is probably mainly mechanical; in fact, equally good results were obtained when a small glass plate was substituted for the sheet-iron, both bodies helping to bring the mercury in contact with the silver sulphide.

Physico-chemical methods have also been used in the analysis of inks. It is customary to extract gallic and tannic acids with ethyl acetate, to free the extract from dissolved ferric chloride by shaking with water, and then to re-extract this aqueous solution with ethyl acetate in order to recover the small quantities of organic acids dissolved. The law according to which a solute divides itself between two solvents shows that exact results cannot be obtained in this way. Better results are obtained by shaking the ferric chloride out of the ethyl acetate extract with a salt solution (*e.g.*, with a half saturated solution of potassium chloride) in which tannic and gallic acids are insoluble. The titration of the extracted acids with iodine in presence of sodium bicarbonate was also studied; constant results are obtained only under certain conditions, as the sodium bicarbonate itself consumes iodine, in quantity depending on the sodium hydroxide formed owing to hydrolysis, which in turn is dependent on time and temperature. Lastly, the

quantity of free acid present in inks may be approximately estimated by salting out the bulk of the colouring matter with sodium chloride and then absorbing the solution in filter-papers previously immersed in indicators sensitive to different concentrations of hydrogen ions.—A. G. L.

Platinum; Alloys of — with the alkali metals and with thallium. L. Hackspill. Seventh Int. Congr. Appl. Chem., London, 1909.

PLATINUM dissolves in sodium and potassium at temperatures above 450° C., and is wholly deposited in a crystalline condition before the solidification of the alkali metal. With thallium, platinum forms a definite compound, PtTl (see this J., 1908, 450), having properties corresponding with those of the lead compound, PtPb, obtained by Bauer, which presents another analogy between lead and thallium.—R. C. P.

Lead; Limit of — in culinary utensils and tinned articles. Padé and Kohn-Abrest. Seventh Int. Congr. Appl. Chem., London, 1909.

VESSELS of tin, such as measures of capacity, intended for daily use may contain such a proportion of lead as is strictly necessary to give a sufficient malleability in the working of the alloy. This quantity, however, should be less than 5 per cent. In the preparation of tin-plate intended for use in the manufacture of preserve-tins and other cooking utensils, the tinning should be made with refined metal, containing not more than 0.5 per cent. of lead and 1 part of arsenic per 10,000. No solder containing lead should be brought into direct contact with the preserved substances.—C. A. W.

Tellurium; Preparation of pure —. [Determination of tellurium in ores.] R. Schelle. Seventh Int. Congr. Appl. Chem., London, 1909.

CRUDE tellurium, containing 30 to 70 per cent. of the element, with copper and antimony as the chief impurities, is boiled with a solution of sodium sulphide with admixture of powdered sulphur. Copper remains undissolved, and pure tellurium is precipitated from the solution by the addition of sodium sulphite. Selenium, arsenic, antimony, tin, gold, and platinum, if present in the solution, are not thrown down. The precipitation is complete, and tellurium may be estimated in its ores, by fusing the ore with sodium carbonate and sulphur, or with anhydrous sodium thiosulphate, extracting with water, and precipitating with sodium sulphite.—A. T. L.

Precipitation of metals by hydrogen from aqueous salt solutions at high temperatures under pressure. W. Ipatjew and W. Werkowsky. Seventh Int. Congr. Appl. Chem., London, 1909. (See also Ber., 1909, 42, 2078—2088.)

For every metal examined, a definite critical temperature has been found, below which it is not precipitated by hydrogen from aqueous solutions of its salts, even when very high pressures (e.g., 600 atmospheres) are employed. Copper is completely precipitated from solution of its sulphate, acetate, nitrate, and chloride only at a temperature of 130°—140° C. At 70° C., however, hydrogen precipitates cuprous oxide from cupric acetate solution, whilst at 120°—130° C., metallic copper is precipitated quantitatively. Nickel is precipitated at 200° C. from solutions of its acetate, sulphate, and chloride, the reaction being incomplete in the last case. Cobalt is precipitated at 180°—200° C. from solution of its acetate and sulphate. Lead and bismuth are completely precipitated at 240°—250° C. Experiments are in progress to study the equilibrium of the reaction:

in presence of hydrochloric acid of sp. gr. 1.19.—A. G. L.

Action of alcohol, its impurities, and denaturant on common metals. Duchemin. See XVII.

Alkali, etc., works report. See VII.

PATENTS.

Smelting zinc ore, galvanizers' dross, etc.; Apparatus for use in —. E. H. Hopkins, Addlestone, Surr. Eng. Pat. 12,403, Nov. 16, 1908.

IN place of the plain tubes containing coke, which is inserted in the ends of the condenser to prevent the escape of zinc fumes, and to trap the lead at the entrance to the condenser, special tubes are used having longitudinal corrugations, internally, externally, or both, where choking of the tubes is avoided. Externally the tubes are of the shape of double cones, or they may be curved so that the condensed lead may be retained in them.—F. R.

Greasy mixtures; Apparatus for eliminating — from solids, or material to be detained, and drying and filtering same. London Electron Works Co., and E. Kardos. London. Eng. Pat. 12,641, June 12, 1908.

METALLIC scrap, or the like, is placed in a vessel having perforated bottom or grid, which is encased in an outer vessel, the latter being filled with water to the level of the grid. The double vessel is closed, and live steam admitted below the grid, causing the grease to liquefy and float to the surface of the condensed water. On opening the outlet pipe in the upper vessel, the released pressure of steam flows through it, carrying by its velocity, part of the condensed water and the whole of the grease floating on it. The heat of the steam left in the vessel, dries the cleansed metallic scrap. The steam and grease pass into another vessel having a number of filter grids, where the steam expands and condenses, depositing the grease on the filters, the heat remaining serving to dry the grease.—F. R.

Defining; Apparatus for preparing scrap tin for —. London Electron Works Co., and E. Kardos, London. Eng. Pat. 12,642, June 12, 1908.

TIN scrap or the like, is placed in the first of a series of five perforated cylinders having their axes in line, and revolving at a small inclination to the horizontal, which causes the material to automatically travel along the length. The material is subjected to a different treatment in each cylinder, viz. 1. Dry and frictional, to remove dry deposit. 2. Sprinkling, from external or internal sprinklers, to remove grease, etc. 3. Washing, the lower portion of the perforated cylinder revolving in an external bath of liquid. 4. Draining. 5. Heating, to remove solder, paint, etc.—F. R.

Tin smelting; Methods and apparatus for —. R. Scott, London. Eng. Pat. 17,229, Dec. 11, 1908.

FINELY-DIVIDED tin oxide is placed in a series of horizontal tubes having their ends fitted with screw caps. The tubes are placed in a furnace with means for rotating them about their long axes. Water-gas or producer gas, is passed through them and they are then heated to reduce and rotated. The tin oxide is reduced to prills of metallic tin, which are subsequently fused into an ingot. The waste heat from the furnace is used for preheating the tubes.—F. R.

Crucible furnaces; Tilting —. J. Newton and Billington, Stoke-on-Trent, Staffs. Eng. Pat. 20,441, Sept. 29, 1908.

THE air holes in the bottom plate or grid of the furnace are arranged concentrically between two raised annular rings integral with the plate, so that the direction of the air blast is controlled, and it does not impinge directly against and cut away the bottom part of the crucible.—F. R.

Pickling metals; Process for —. G. K. Davis and R. Fearon, Manchester. Eng. Pat. 25,024, Nov. 1908.

SULPHURIC acid of about 110° Tw. is added to the previously used hydrochloric acid pickling bath, (which is preferably at 45° to 50° C.) in order to convert the dissolved metal chlorides into sulphates and set free hydrochloric acid for further use. When the bath is saturated with

lphates, the sulphates are allowed to crystallise out, and the residual liquor made up with water and acid to the original volume.—F. R.

Silicon [tellurium] alloy. J. T. H. Dempster, Schenectady, N.Y., Assignor to General Electric Co., New York. U.S. Pat. 923,152, June 1, 1909.

An alloy of silicon with 1–15 per cent. of tellurium is produced by melting together silicon and tellurium in presence of a material (e.g., a decomposable carbonate) which will combine with silica to form a protective layer of slag upon the fluid mass. A decarburising agent may be added.—A. G. L.

Leels; Heat treating and quenching alloyed —. J. Churchward, Mount Vernon, N.Y., U.S.A. Eng. Pat. 17,759, Aug. 24, 1908.

Alkaline salts from blast-furnace tar. Eng. Pat. 16,690. See VII.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Manganese; Electrochemical behaviour of —. C. N. Otin. Z. Elektrochem., 1909, 15, 385–386.

WHEN manganese salts are electrolysed with high current densities, weighable amounts of manganese are often deposited on the cathode. Different salts behave differently in this respect, the amount of cathodic deposition being less with the nitrate or the double ammonium sulphate than with the sulphate. The addition to the liquid of a sufficient amount of ammonium sulphate completely prevents this cathodic deposition in all cases. —J. T. D.

Manganese; Electrolytic determination of —. C. N. Otin. Z. Elektrochem., 1909, 15, 386–389. (See preceding abstract.)

THE whole of the manganese from pure manganese salts (sulphate, nitrate, manganese-ammonium sulphate) can be obtained on the anode as a coherent deposit of pure anhydrous peroxide, under the following conditions:—Cathode, platinum spiral of 17–18 sq. cm. surface; anode a platinum basin with matt surface; voltage about 4 (two accumulators in series); current density 0.1 to 0.8 ampere per 100 sq. cm. of anode; time, about 12 hours at ordinary temperature or about 2 hours at 60°–65° C.; amount of salt corresponding to 0.3–1.0 gm. of manganese dioxide; addition to bath, 1–2 grms. of ammonium sul-

phate and 3–8 c.c. of alcohol. At the end of the electrolysis the deposit is carefully washed with water, dried till of constant weight (1½–4 hours) at 200°–220° C., and weighed with the basin. Without the addition of alcohol the deposit is not so firmly adherent, though even then it is dense enough to allow of washing by decantation without loss. When alcohol is added the deposit shows a deficiency of oxygen, too slight, however, to affect the result as determined by the weight of the deposit. —J. T. D.

Electrolytic oxidation of ammonia. Brochet and Boiteau. See VII.

PATENTS.

Electric cables; Manufacture of — and of material for use therein. E. S. Ali-Cohen, Nymwegen, Holland, P. A. M. Cramer, Amstel, Holland, and W. Geipel, London. Eng. Pat. 10,535, May 14, 1908.

THE electric cable, comprising one or more conductors, is covered with layers of paper tape coated with a semi-liquid bituminous insulating material, and, if necessary, textile fabric, impregnated or not with insulating material, may be interposed between the layers of coated paper, and also wound round the cable as an outer protective covering. The waterproofing and insulating material may be such as is described in Eng. Pats. 8071 of 1902 or 5279 of 1908 (this J., 1903, 425; 1908, 816), with liquid paraffin in such proportions as to render the mixture semi-liquid at ordinary temperatures; e.g., comprising 63 per cent. of purified asphaltum, 18.4 per cent. of solidified petroleum, and 18.6 per cent. of liquid paraffin. Such a material, when wound in concentric layers, forms a cable which will resist injury due to bending or like strains, owing to the flowing action of the bituminous substance. If necessary, the cable may be afterwards vulcanised by heating.—R. N.

Galvanic element of the Bunsen type. K. Heintz, München, Germany. Eng. Pat. 13,671, June 27, 1908.

IN place of nitric acid for the depolarising solution, a solution of sulphuric acid, 30 per cent. or higher, with nitric acid of 36° or 40° B. is used. This mixture depolarises until the nitric acid is quite used up and can be renewed by the addition of nitric acid and concentrated sulphuric acid in approximately equal parts by weight. For continuous operation the exciting solution should consist of a neutral solution of zinc or iron sulphate, in place of the usual 5 per cent. sulphuric acid solution.—F. R.

Cell or condenser; Electrolytic —. E. E. F. Creighton, Schenectady, N.Y., Assignor to General Electric Co., New York. U.S. Pat. 923,774, June 1, 1909.

THE condenser consists of a number of water-tight cups of aluminium, arranged one within another, and separated by a solution of citric acid. The whole is surrounded by an oil-bath, which insulates the edges of the cups and leaves a free passage for the escape of gases.—A. G. L.

Electric conductors; Manufacture of refractory —. W. D. Coolidge, Schenectady, N.Y. Eng. Pat. 17,621, Aug. 21, 1908. Under Int. Conv., Aug. 24, 1907.

TUNGSTEN or other suitable metallic powder is incorporated with a ductile alloy or other metallic binder and formed into conductors. The latter are then heated in an oven or furnace until the alloy is vaporised and the tungsten is sintered into a coherent body.—W. H. C.

Furnaces; Electric — for the treatment of gases or gas mixtures. Salpetersiure Ind.-Ges. m. b. H., Gelsenkirchen, Germany. Eng. Pat. 8443, April 7, 1909. Under Int. Conv., May 22, 1908.

THE furnace comprises a series of superposed annular elements, alternately provided with air inlet orifices and gas suction pipes, and surrounding an axial shaft, at the extremities of which the electrodes are placed. The elements having gas suction pipes are box-like, and contain cooling coils, or equivalent cooling apparatus.

surrounding the shaft, for the purpose of cooling the gases sucked through, but the gas outlet orifices nearest the electrodes communicate with a conduit separate from the main gas conduit.—B. N.

Filaments. Eng. Pat. 27,144. See 11.

(B.) ELECTRO-METALLURGY.

One [Iron]; Electric furnace reduction of —. J. W. Richards. Amer. Electrochem. Soc., Niagara Falls, May, 1909. *Electrochem. and Met. Ind.*, 1909, 7, 253-254.

The author compares the reduction process in the blast-furnace with that in the electric furnace. In the case of the first, the combustion of the carbon to carbon monoxide before the tuyères fulfils two functions; it provides the high temperature necessary for the smelting of the iron and slag, and it generates a large quantity of reducing gas which performs in the upper part of the furnace the greater part of the reduction. The amount of fuel used in a blast-furnace is determined solely by the amount which must be burnt at the tuyères in order to produce the necessary temperature. From this it can be shown that only one-third of the carbon monoxide produced at these points is used in the reduction of the ore, the remaining two-thirds escaping unchanged. On the other hand, in the electric furnace, where there is no blast and where the heat is supplied from outside by electrical energy, practically the whole of the solid carbon is utilised for reduction. It can then be shown that the amount of carbon utilised in the electric furnace is between one-third and one-fifth of that required in the ordinary blast-furnace, according as the reaction takes place in the hottest parts, with sole production of the monoxide, or in the cooler portions, where a mixture of dioxide and monoxide is produced. Since no air is blown into the electric furnace, any excess of carbon above that consumed in the reduction must remain unused, accumulate, and tend to clog the furnace. The author therefore recommends a combination of blast and electric furnace provided with a variable supply of air. Under ordinary conditions this supply would be a minimum and only sufficient to keep the tuyères open, the full blast being turned on when the falling resistance of the furnace indicated an accumulation of carbon.—C. A. W.

Steel; Automatically circulating furnaces of the Gin type for the electrical production of steel. G. Gin. Faraday Soc., 1909, June 15. [Advance proof.]

Induction furnaces are described in which the molten material is in continual circulation, thus causing a better distribution of heat and of the purifying reactions than in the ordinary induction furnace. The furnaces are composed of two crucibles communicating by inclined channels, the whole arrangement forming a closed circuit in which the heat generated causes a general circulation. Every portion of the molten mass comes rapidly into contact with the oxidising slag, and the very high temperature attained does not introduce the "pinch" effect in the heating channels. It is claimed that with this type of furnace the ohmic resistance of the circuit can be increased with corresponding alteration of the self-induction, thus allowing furnaces with a high-power factor to be constructed, and generators and transformers of normal frequency and size to be employed. A 5-ton, 420-k.w. furnace is illustrated, designed to take current at 4800 volts at a frequency of 5. The author also describes an electrode furnace in which the same system of automatic circulation is applied, by cross-connecting the separate crucibles, into which the electrodes dip, by means of inclined channels, sloping in opposite directions. Finally, the author describes a combined induction and electrode furnace similarly arranged for automatic circulation of the fluid steel. In this, internal heating in the channels, generated inductively, and superficial heating at the electrodes in the two connected crucibles are simultaneously made use of. To the paper is added an appendix which gives the calculations necessary for the design of these types of furnaces.

Silicon sulphide in the desulphurisation of iron; Formation of —. W. Fielding. Trans. Faraday Soc., June 15, 1909. [Advance proof.]

In order to ascertain why the addition of ferro-silicon, in the refining of steel in the electric furnace, assisted complete desulphurisation, a mixture of pure ferrous sulphide and ferro-silicon was placed in a graphite tube and heated in an electric resistance furnace. Carbon monoxide was first evolved and at 1700° C. a yellow vapour was given off, which partly condensed in the tube, the carbon monoxide when ignited smelling strongly of sulphur dioxide. The yellow substance was found to contain about 50 per cent. of silicon sulphide (SiS₂), as determined from the amount of sulphuretted hydrogen evolved on the addition of water, the remainder being ferrous sulphide, silica, and a little ferric oxide. Under reduced pressure the sublimate began to form at 1500° C., but the silicon sulphide could not be obtained pure as even *in vacuo* no volatilisation occurred up to 1100° C., above which temperature the iron sulphide also volatilises.—F. R.

Vanadium; Production of —. G. Gin. Amer. Electrochem. Soc., Niagara Falls, May, 1909. *Electrochem. and Met. Ind.*, 1909, 7, 264.

By the electrolysis of a solution of vanadium trioxide in fused calcium fluovanadate, V₂F₆·3CaF₂, metallic vanadium is obtained, the principle being analogous to that employed in the manufacture of aluminium. The lining of the bath is composed of pure electrically fused alumina agglomerated with tar and a little vanadic anhydride. Carbon anodes are employed, and the cathodes are composed of conical conductors of pulverised and agglomerated ferro-vanadium. On these the metal is deposited in solid sheets which are subsequently removed when the bath has been emptied. A current density of 4.5 amperes per square inch of anode section is recommended.—C. A. W.

Silico-vanadium. G. Gin. Amer. Electrochem. Soc., Niagara Falls, May, 1909. *Electrochem. and Met. Ind.*, 1909, 7, 264.

The silicide, SiV₂, was obtained by reducing in an electric furnace a mixture of vanadic acid (10 parts), silica (1 part), and coke (1 part). The current density employed amounted to 1290 watts per square inch of cross-section of electrodes. The volatilisation of vanadic acid could be almost prevented by using vanadium trioxide, according to the equation:

Employing an intimate mixture of rich ferro-silicon with the trioxide, the whole being agglomerated with 4 to 6 per cent. of coal-tar pitch and charged into the furnace in the form of briquettes, a double silicide of the approximate composition, Fe₄Si₅V₆, was obtained.—C. A. W.

PATENTS.

Electroplating; Apparatus for —. R. E. Phillips. London. From The Meaker Co., Chicago, Ill. Eng. Pat. 5087, March 2, 1909.

The articles to be plated are continuously passed, during the process of plating, through the bath, and means are provided for rotating or turning the articles, in order to direct every portion toward the anodes and prevent uneven deposition of metal.—B. N.

Metals; Process for the electric dissociation [deposition] of — by the wet method. A. Levy. Paris. U.S. Pat. 923,861, June 8, 1909.

SEE FR. Pat. 385,058 of 1907; this J., 1908, 818.—T. F. B.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Fatty acids of fish oils. L. M. Tolman. J. Ind. and Eng. Chem., 1909, 1, 340-345.

The oils used in the investigation were Norwegian and American cod-liver oils, pollock-liver oil, hake-liver oil,

ing-liver oil, dogfish-liver oil, trout-liver oil, and seal blubber oil, all of known origin and purity. Determinations were made of the iodine value (Hanus), saturated fatty acids, and the brominated fatty acids and glycerides insoluble in ether and petroleum ether respectively. For the determination of the brominated compounds precipitate, very satisfactory results were obtained by separating the precipitate by means of a centrifugal machine. Comparison of the bromine precipitates obtained from the fatty acids and from the glycerides respectively indicates that the oils contain mixed glycerides. There is a remarkable similarity among the oils from salt-water fish, fresh-water fish, and animals, such as the seal, which live chiefly on fish. (See also his J., 1906, 382).—A. S.

Halphen's reaction [for cottonseed oil]; Modification of —. L. Garnier. Ann. Chim. analyt., 1909, 14, 209—210.

MORE definite results may be obtained with Halphen's reaction by employing a suspension of sublimed sulphur 2 per cent. in carbon bisulphide, instead of the 1 per cent. solution originally prescribed, and by comparing the maximum depth of colour obtained under definite conditions with a series of colour standards previously prepared. The carbon bisulphide and sulphur reagent is well agitated and measured off quickly, an equal volume of the oil and of amyl alcohol are then added in a tube of 25 mm. diameter and 20 c.c. capacity. The height of the liquid (9 to 10.5 c.c.) is then marked with a diamond, the tube is attached to a reflux condenser, and heated for one hour in a boiling water bath. On cooling, a slight deposit of sulphur is formed. The mixture is then made up to its original volume by the addition of a little carbon bisulphide, and the depth of colour noted. Standard tubes are prepared by the above method containing 5, 10, 20, 25, 30, 40, 50, 75 and 100 per cent. of cottonseed oil, the diluent being an indifferent oil, such as poppy seed oil. These standards should be kept in the dark, in well corked tubes of 14 to 15 mm. internal diameter. The presence of an excess of sulphur in the reagent ensures the production of a maximum depth of colour under the above conditions.—J. O. B.

Wax plant; New —. J. Soc. Arts, 1909, [2953], 66.
It has been recently found that the candleilla plant contains wax of good quality, and in sufficient amount to make it valuable. The plant is found growing in the following States of Mexico: Tamaulipas, Coahuila, Nuevo Leon, Chihuahua, Durango, Zacatecas, Sonora, Sinaloa, Baja California, Jalisco, Puebla, and San Louis Potosi. It is said to contain from about three and a-half to five per cent. of a wax of a light colour, very hard, and with a high melting point. It is stated that the wax can be leached perfectly white, and that on burning it gives off an agreeable odour.

Cottonseed and sesamé oils; Importation of — into Australia. Board of Trade J., June 24, 1909. [T.R.]

AN Australian By-law (No. 43) of May 5th last, provides that thickened cottonseed oil used solely in the manufacture of other non-edible oils, may be admitted to duty into the Commonwealth under item 234 (1) of the Customs tariff (*viz.*, 6d. per gall.) when denatured by addition of—
a) The equivalent of 5 per cent. of its bulk of mineral lubricating oil of sp. gr. 86 at 60° F., or (*b*) The equivalent of 10 per cent. of its bulk of mineral lubricating oil of less than the sp. gr. quoted. A Customs notice dated May 5, 1909, directs that a duty of 2s. per gallon shall be charged on sesamé oil on importation into Australia.

Soya bean oil and oil cake. Ch. of Comm. J., July, 1909. [T.R.]

CHINESE Soya beans during the last few months have been imported into the United Kingdom in large quantities. Extensive areas of land in China and Manchuria are cultivated for this crop; the plant possesses the property, common to leguminous plants, of absorbing nitrogen from

the air with the result that its cultivation exhausts the soil far less than other oleaginous plants. The oil-pressing mills at Hull have already imported large consignments and, it is stated, find the oil a valuable product. The oil obtained is of good colour and the residual cake is an excellent cattle food. The price of Soya beans has been up to the present very low on account of the abundance of the product. The quantity of beans already exported this year is estimated at over 150,000 tons, and there are at the present time many cargoes of 4,500 to 6,000 tons from Vladivostok and Dalny on the way to Europe, consigned to Hull, Liverpool, and Hamburg. The condition of the beans on unloading is stated to be perfect, in spite of the long voyage. The product is sold with a guaranteed maximum of 2 per cent. of non-oleaginous foreign matter; it is packed in the original sacks. The qualities are classified in three grades: No. 1, shipped at Dalny; No. 2, at Vladivostok; and No. 3, at Hankow. The value of No. 1 is about 12s. 7d. per 100 kilos, gross, c.i.f. European port direct. Nos. 2 and 3 are of equal value, about 12s. 5d. per 100 kilos, gross. In addition to the excellent results which have been obtained with the oil expressed from the beans, the Soya bean cake has met with great success in this country as a cattle food of the first quality rich in albuminoids. It is used as cake or in the form of meal. The following analysis of the cake has been given: Albuminoids, 44.37 per cent., containing 7.10 per cent. of nitrogen; carbohydrates, 32.36; fibre, indigestible, 4.57; mineral matter, 16.70 per cent.

Oils and fats; industry and analysis. J. Lewkowitzsch. Bull. Soc. Chim., 1909, 5, [10], i.—xliv.

THE author reviews the chemistry, industry, and analysis of oils and fats, with relation to their French aspect, touching among other points on the natural occurrence of mixed glycerides, the "alcoholysis" of oils and fats, rancidity, formation of fatty acids from petroleum hydrocarbons, manufacture of butter substitutes, stearine candle industry, conversion of oleic acid into stearic acid, and manufacture of soap and glycerin. In discussing the hydrolysis of oils and fats, he emphasizes the points: (1), that the actual hydrolysing agent in all processes is water, the acids, bases, or enzymes used acting as catalytic agents; and (2), that the hydrolysis proceeds in three stages, each of which is a bimolecular reaction. As examples of the influence of environment on the oil-content of seeds, the author mentions that in the United States two kinds of maize have been developed: one containing as much as 6.53 per cent., and the other as little as 2.97 per cent. of oil; also that American and Egyptian cottonseed containing about 23 per cent. of oil, when transplanted and cultivated at Bokhara, yields only 17.5 per cent.

With regard to the analysis and characterisation of oils and fats, Bömer's phytosteryl acetate test serves to distinguish vegetable from animal products, and the iodine values may be used to divide oils and fats into the groups of drying, semi-drying, and non-drying products, which groups may be further subdivided by other methods. A scheme of classification is shown in the following synoptic table:—

I. VEGETABLE OILS AND FATS.	II. ANIMAL OILS AND FATS.
A.— <i>Vegetable oils.</i>	A.— <i>Animal oils.</i>
1. Drying oils.	1. Marine animal oils:—
2. Semi-drying oils:—	(a) Fish oils.
(a) Cottonseed oil group.	(b) Liver oils.
(b) Rape oil group.	(c) Blubber oils.
3. Non-drying oils:—	2. Terrestrial animal oils:—
(a) Almond oil group.	(a) Semi-drying oils.
(b) Olive oil group.	(b) Non-drying oils.
(c) Castor oil group.	
B.— <i>Vegetable fats.</i>	B.— <i>Animal fats.</i>
1. Chaulmoogra oil group.	1. Drying fats.
2. Laurel oil group.	2. Semi-drying fats.
3. Palm oil group.	3. Non-drying fats:—
4. Nutmeg butter group.	(a) Body fats.
5. Cacao butter group.	(b) Milk fats.
6. Coconut oil group.	
7. Dika fat group.	

Vegetable drying oils are characterised by their content of linolenic acid, and semi-drying oils by their content of linolic acid. The cottonseed oil and rape oil groups

are differentiated by their saponification values, those of the latter class being lower owing to the presence of erucic acid. The vegetable non-drying oils contain a preponderance of oleic acid, with the exception of the castor oil group which contains considerable amounts of ricinoleic or other hydroxy acids. The almond oil group contains small quantities of linolic acid. Of the vegetable fats, the chaummoogra oil group exhibits optical activity; the laurel oil group contains considerable quantities of oleic acid; the palm oil group contains large amounts of palmitic acid, the nutmeg butter group, of myristic acid, and the cacao butter group, of stearic acid. The coconut oil group contains lauric

acid and notable quantities of volatile acids. The dika fat group contains a preponderance of lauric acid with little or no volatile acids. Of the animal oils, those of marine animals are characterised by the presence of chupanodonic acid, and those of terrestrial animals, by that of oleic acid. Drying and semi-drying animal fats contain acids less saturated than oleic acid. Of the non drying animal fats, the milk fats are distinguished from the body fats by the presence of volatile acids.

In the following table the French imports and exports of oil-seeds, fatty substances, and products derived there from are given in metric tons (except where otherwise stated) for 1906, 1907, and 1908.

	Imports.						Exports.

NOTE.—Commerce général represents for imports all goods imported, and for exports all goods exported, without any deduction for goods that only go through the country in transit.

Commerce spécial.—The imports represent the national consumption of the imported goods, either for actual consumption as foodstuffs, or as raw material for home industries. The exports represent the national production.

Glycerin. British and Col. Drug., June 18, 1909. [T.R.]

THE price of chemically pure glycerin has been raised to £75 per ton, and sales of "crude" have been reported from Paris at £60, forward delivery. The scarcity of crude, which is the origin of the rise in price, is traceable to a number of causes. The substitution of paraffin wax for tallow in candle manufacture is coincident with a marked increase in the consumption of glycerin for explosive and blasting purposes. The gold output in South Africa increases every month, notwithstanding that the ore is poorer and deeper, and has to be blasted more extensively. Before the Boer War South African requirements in dynamite-glycerin were 2500 to 3000 tons per annum, whereas to-day they are 6000 tons. Canada eight or nine years ago took 400 to 500 tons, as against 1200 tons or more now. Constructional work on the Panama Canal is also attracting large quantities. The United States is reported to be in the market for more than 3,000 tons of crude, and requires for home consumption more glycerin than it produces. The quantity of crude imported therein during the last decade has ranged from 12,000 to 39,000 tons, the maximum being reached two years ago. There are also many contracts for the explosives industry to be arranged in the forthcoming autumn.

It seems, therefore, that an expansion of demand in conjunction with restricted supplies has placed glycerin at a very high value, which will obtain for some time. Controlling explosive interests in Europe require approximately 9000 tons of crude, and in America about the same; it is possible that they might unload small quantities in order to depress the market for their 1911 purchases. Such an operation could, however, have no lasting effect. On the other hand, most countries are working on new processes for the manufacture of high explosives in which glycerin is not required, and the prevailing high price is hastening their advent.

Solvents; Chlorine derivatives of ethane and ethylene and their industrial importance as non-inflammable non-combustible and non-explosive — G. Koller. Seventh Int. Congr. Appl. Chem., London, 1909.

THE chlorine derivatives of ethane and ethylene are non-combustible, non-inflammable, and non-explosive solvents of oils, fats, resins, etc., with a wide range of boiling points. Their use ensures absolute safety and combines the advantage of lower freight rates with a total absence of vexatious restrictions.

Chinese wood oil; Examination of — E. W. Boughton. Seventh Int. Congr. Appl. Chem., London, 1909.

SEVEN samples of tung oil were examined, six being received directly from China and the seventh pressed from the imported nuts. The constants obtained agreed with those published by other observers, except the iodine value. This was found to vary greatly, if Hanus or Wijs solution was used, the temperature, time of contact, and ratio of iodine solution to oil affecting the result. If the Hübl solution be used, however, the variation is small, and the values thus obtained fell within the limits of those published by other observers. The oxygen absorption of Chinese wood oil (Livache test) is much less than that of linseed oil in 48 and 96 hours. On heating tung oil in the steam oven for one hour the gain in weight is greater than for linseed oil. The Lieberman and Storck rosin test gives with Chinese wood oil a claret colour. Ten per cent. of tung oil may be detected in a mixture of tung and linseed oils by either of the following methods: 1. Place ten c.c. of oil in a test tube. Add ten c.c. of a saturated solution of iodine in chloroform. Heat in steam bath till chloroform is expelled. Then heat one hour in oil bath at 200° C. Pure linseed oil remains liquid, while ten per cent. of tung oil will cause solidification. 2. In a glass stoppered tube place ten c.c. of the oil. Add ten c.c. of strong nitric acid and shake well. Place in ice water for one hour. If as much as ten per cent. of tung oil be present, the oily layer will be semi-solid.

Coconut oil; Constituents of aqueous distillates from —

A. Haller and Lassieur. Seventh Int. Congr. Appl. Chem., London, 1909.

IN the purification of coconut oil by treatment with a current of steam, the volatile products expelled consist of acids and of neutral substances insoluble in alkali solutions. The latter have the characteristic odour of the fat, reduce ammoniacal silver nitrate, and combine to a small extent with sodium bisulphite. When distilled under reduced pressure (15 mm.), fractions are obtained with b. pts. from 85° to 106° C., but the main portion distils at 105°–106° C. This consists of a ketone, $C_{20}H_{40}O$, melting at 8° C., and forming a semicarbazone (m. pt., 122° C.), and an oxime (m. pt., 44° C.). The acetate of this oxime distils at 164° under a pressure of 15 mm. The ketone offers great resistance to oxidising agents, and is scarcely attacked by manganese dioxide and sulphuric acid. It is decomposed, however, by silver oxide in the presence of potassium hydroxide, with the formation of a liquid acid, the silver salt of which has the formula, $C_9H_{17}O_2 Ag$.—C. A. M.

Methyl ricinoleate; Oxidation of — by means of ozone.

A. Haller and A. Brochet. Seventh Int. Congr. Appl. Chem., London, 1909.

OZONISATION of methyl ricinoleate in the presence of 10 per cent. of water yielded a white ozonide, $C_{19}H_{36}O_7$, melting at 80° to 85° C. On systematic treatment with sodium carbonate and sodium bisulphite, this yielded the following products:—(1) Active hydroxynonylic acid melting at 47°–48° C. (2) Azelaic acid. (3) Methyl azelaate. (4) A compound of sodium sulphite with the methyl ester of the semi-aldehyde of azelaic acid. (5) A sodium sulphite compound, which was readily soluble in water, and on decomposition with sulphuric acid yielded a product that could be oxidised by potassium permanganate into heptylic acid. (6) A liquid residue insoluble in sodium carbonate solution and not combining with sodium bisulphite. This consisted of a mixture of methyl palmitate and stearate.—C. A. M.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

White lead; Electrolytic production of — J. A. Yuncik. Amer. Electrochem. Soc., Niagara Falls, May, 1909. Electrochem. and Met. Ind., 1909, 7, 274.

THE process employed is, briefly, to electrolyse a solution of sodium nitrate, ammonium nitrate, or a mixture of both between anodes of lead and cathodes of aluminium, these being cast in the form of strips and grids connected at top and bottom in order to facilitate a continuous operation. The tank is water-cooled from the outside, and provided at the bottom with a stirring device, so that a slow steady motion of the solution is obtained. During the electrolysis carbon dioxide gas is passed through the electrolyte from small orifices in the lower part of the tank. The nitrate decomposed is continually re-formed, so that the only materials consumed are lead, carbon dioxide, and water. The current density employed is 10 amperes per square foot of anode surface at from 1 to 2 volts. After 2½ hours the operation is stopped, the precipitated white lead allowed to settle, removed, washed, and dried. It is stated that 1 ton of white lead requires for its production 16 kw.-hours and that the product is finer than any producible by mechanical means. By employing as anodes lead in combination with copper, nickel, or iron, pigments of various shades and colours can be obtained.—C. A. W.

(B.)—RESINS, VARNISHES.

Oil varnishes; Recent progress in manufacturing —. C. Collignier. Seventh Int. Congr. Appl. Chem., London, 1909.

The author states that of various methods hitherto proposed for the manufacture of oil varnishes without previous heating, only one has led to successful results, *viz.*, that in which naphthalene under pressure is employed, or by using a mixture of naphthalene and copal oils, or rosin oil, with or without pressure. (See this J., 1906, 939.)

India turpentine factories. Ch. of Comm. J., July, 1909. [T.R.]

It is announced that the Government turpentine factory at Dehra Dun, United Provinces, will soon close down and cease operations. The Government factory at Nampur was also abandoned after six years of operation. One turpentine factory in operation in the United Provinces seems to be doing well. Recent improvements have doubled the capacity of the factory. The manufacture of turpentine in the Himalaya mountains is profitable, provided the business is carried on economically and in a modern way.

PATENTS.

Varnish-gum and producing same. J. J. Kessler, St. Louis, Mo. U.S. Pat. 922,596, May 25, 1909.

The varnish is prepared by treating rosin with nitric acid, washing the product thoroughly with water, drying it, and dissolving it in a suitable solvent.—W. P. S.

Vulcanised rubber; Method of determining combined sulphur in —. T. Budde. Gummi-Zeit., 1909, 23, 1143—1144.

The author refers to the possibilities of inaccuracy in the estimation of combined sulphur in vulcanised rubber, as ordinarily carried out. Moreover, he suggests that, even in the case of a pure rubber-sulphur mixing, it is not possible to obtain an accurate result by estimating the sulphur present in the acetone-extracted sample, since the whole of the free sulphur is not extracted by acetone; this may be due either to insufficient penetration of the rubber sample by the acetone, or, more probably, to a portion of the free sulphur having been converted into an insoluble form during vulcanisation; the figures ordinarily obtained for combined sulphur are therefore too high. In further investigation of this possibility, comparative estimations of the combined sulphur in a number of samples of vulcanised rubber by the ordinary method, and by a method based on the tetrabromide process (see also Hübener, this J., 1909, 251) have been made.

One grm. of the sample was soaked in 30–40 c.c. of carbon tetrachloride for 24 hours, and 250 c.c. of Budde's bromine solution were then added. (This solution is composed of 1 litre of carbon tetrachloride, 6 c.c. of bromine, and 1 grm. of iodine). The mixture was allowed to stand for 6 hours, and about half its own volume of alcohol was then added to it, after which it was allowed to stand for a further 12 hours and then filtered. The insoluble bromine-sulphur-rubber derivative was allowed to stand in contact with 10 to 15 c.c. of bromine for 24 hours, when it was found to be completely dissolved. Water was added, and the bromine driven off by gently heating on a sand-bath. By this means the whole of the

sulphur present, except that actually combined with the rubber, is eliminated as sulphuric acid, and the combined sulphur can then be estimated in the bromine-sulphur compound, after this has been thoroughly washed with boiling water by decantation, then with alcohol and ether, and dried. The Henriques' method, as modified by Frank and Marekwald, (Gummi-Zeit., 1903, 17, 71) was used by the author for the sulphur determinations. In four different samples of vulcanised rubber, the results obtained by the new method and by the old acetone-extraction method were as follows:—(1), 3.85, 2.14; (2), 3.36, 1.52; (3), 4.63, 2.85; (4), 4.06, 2.01 per cent. — E. W. L.

Indiarubber in North America. H. C. Pearson. Seventh Int. Congr. Appl. Chem., London, 1909.

In the indiarubber industry, the American practice has been to concentrate on special lines. The investment of about \$20,000,000 in rubber plantations in Mexico and Central America, and the production of rubber from the guayule plant—*Parthenium argentatum*—in the uplands of Mexico, are interesting developments in the crude rubber industry. The utilisation of rubber waste has been carried further in America than in other countries, so that the whole of this material has a market value.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Tannery; Sources of error in the —. B. Kohnstein. Gerber, 1909, 35, 141—143.

The author discusses the many "sources of error" which produce exudations on leather. The use of mineral salts in many ways can cause disagreeable exudations on leather. The employment of alkali in the washing processes or for the removal of fat from skins, the use of alum, salt, saltpetre, etc., to hasten the tanning, bleaching with lead acetate, tin salts, or oxalic acid, the impregnation

of leather with crystallisable salts such as barium chloride, magnesium sulphate, zinc sulphate, etc.—these processes are among many enumerated by the author as being dangerous in the above respect. In the manufacture of two-bath chrome leather, trouble may be encountered by the appearance of a sulphur exudation, and an instance is quoted of a case of white shoes, in which the lead acetate used in bleaching the upper leather came in contact with, and was acted upon by the sulphide in the chrome sole, producing black lead sulphide. The author further deals with fat exudations, the formation of calcium soaps, by the action of lime on the natural fat of certain skins, and the action of free fatty acids on metallic bases.

—S. H.

Tanning analysis; Report on — of the Commission appointed by the German Section of the Internat. Assoc. Leather Trades Chemists. J. Paessler. Collegium, 1909, 201—208.

SAMPLES of chesnut, pine bark, myrobalan, solubilised quebracho, and ordinary quebracho extracts were supplied to the members of the Commission, and these were analysed by four methods, viz.: (1), by the use of American white hide powder, chromed, washed and used in the shake apparatus; (2), by the use of Freiberg white powder used in the same way; (3), by the use of Freiberg lightly chromed powder which only requires washing; and (4), by the use of the latter powder according to the method suggested by Zeuthen (Collegium 1908, 366). In the "blank" control tests, with one or two exceptions, high figures are obtained by all four methods, and poor concordance is shown between results obtained by different operators. Tables of results of analyses of the above extracts, obtained by the different methods are given. It is stated by the author, that, while, on the average, all the methods give very similar percentages of non-tannins, greater concordance is obtained by the use of Freiberg chromed powder, and by Zeuthen's method, than by the present official method.—S. H.

Acid determination [in tannery liquors]. Note on the gelatin-hematin method of —. W. K. Alsop. J. Amer. Leather Chem. Assoc., 1909, 4, 173—175.

THE gelatin-hematin method for the determination of acidity of tan-yard liquors (see this J., 1908, 1166), is at present being tested by American leather chemists and the author gives a table of determinations made by himself, upon liquors from 23 tanneries, which are representative of the liquors used in the country. It is shown that when the liquors are distilled and the volatile acid estimated in the distillate, and the non-volatile in the residue, results are obtained closely agreeing with those obtained for total acidity in the original liquor. Moreover, results obtained from samples made by mixing equal volumes of 5 or 6 liquors from each tannery, also agree well with results obtained in the course of routine work, representing the amount of acid shown by averaging that found in the individual samples that were mixed.

Lactic acid in America. McLanchlan. See XVII.

PATENTS.

Shaving, smoothing, whitening, polishing and cleaning hides and similar materials. Machines for —. The Turner Co., Ges.m.b.H. Fr. Pat. 397,062, Dec. 3, 1908.

THE operating roller of the machine is mounted in the upper open end of a hollow casing, in the lower part of which is a fan or other aspirating device, so that all dust, scrapings, etc., removed from the material are drawn into and collected in the hollow casing. The operating roller is partially surrounded by a hood which, at the part where the roller will come in contact with the material to be treated, is provided with an opening the size of which can be regulated by an adjustable plate. According to the object in view, the operating roller is furnished with blades, or it is covered with emery cloth or similar

material; in the latter case it is constructed in two parts, hinged together, in order to allow of the ready replacement or removal of the emery cloth. The roller used to support the hide is prepared by mounting a series of discs or rings of felt or other suitable material, close together on a central axis; it is so supported that, by means of a lever, it can be brought in contact with the operating roller.—A. S.

Tanned hides and skins; Treatment of —. G. B. M. Spigno. Fr. Pat. 397,650, Dec. 19, 1908. Under Int. Conv., Dec. 21, 1907.

THE tanned skins are treated in a bath containing glue or gelatin free from iron and lime, or the glue or gelatin, or substances containing gelatin, may be added to the ordinary finishing preparations. Or, the skins may be treated with glue or gelatin after having been passed through one tanning bath and before passing through another. After the treatment with glue or gelatin, the skins may be treated with a solution containing a fixing agent, e.g., formaldehyde.—A. S.

Keratin composition; Thermoplastic —. B. B. Goldsmith, New York. U.S. Pat. 922,692, May 25, 1909.

KERATIN is mixed intimately with β -naphthol and the mixture is then subjected to heat and pressure.—W. P. S.

Thermoplastic compound and method of making same. B. B. Goldsmith, New York. U.S. Pat. 924,057, June 8, 1909.

A VEGETABLE albuminoid substance is mixed with a non-hygroscopic converting agent such as β -naphthol, and the mixture is subjected to heat and pressure.—A. S.

XV.—MANURES, &c.

Soils; Changes produced in — by subjecting them to steam under pressure. T. L. Lyon and J. A. Bizzell. Seventh Int. Congr. Appl. Chem., London, 1909.

THE soils, clay loam, sandy loam and silt loam, were heated in an autoclave under two atmospheres' pressure for two or four hours. Steaming increased the water soluble organic and ammonia nitrogen, total ammonia nitrogen, nitrites and total soluble matter, the latter consisting largely of organic matter. The nitrates, however, were decreased by the treatment. On standing 56, 82, or 90 days there were decreases in the soluble matter, soluble and ammonia nitrogen and nitrites, while the nitrates remained practically constant. Wheat grown in the steamed soils appeared at first to be injured by the treatment, but subsequently recovered, and at the end of the experiment was much superior to that grown in the unheated soils. The sandy loam was first to recover, the clay next, and the silt last. The injury seemed to be mitigated somewhat when the steamed soil was inoculated by an infusion of the fresh soil. Plants grown in extract made from steamed soil gave poor growth. Injurious substances seemed to be produced during the steaming process. In the unsteamed soils there was a loss of total soluble matter where crops were grown, but in the steamed soils the reverse was true.

Soil potash. G. S. Fraps. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1908, 634.)

POTASH minerals were studied to determine the source of the potash dissolved from the soil by various solvents. Nephelite, leucite, glauconite and biotite gave up all their potash to strong hydrochloric acid. Microcline and orthoclase gave up very little. The potash dissolved from the soil by strong acids comes chiefly from biotite, hydrated silicates, or muscovite. Muscovite, nephelite and leucite give up 15 to 60 per cent. of their potash

to N/5 nitric acid, glauconite and biotite less than 10 per cent., and microcline and orthoclase practically none. Potash absorbed by zeolites was highly soluble in N/5 nitric acid, but not completely removed. Although some of the potash dissolved by N/5 nitric acid is removed from solution by the fixing particles of the soil, the percentage of fixation is in no case large.

Potassium: Orthoclase, mica, and nepheline as sources of — for plants. D. Prianichnikov. Seventh Int. Congr. Appl. Chem., London, 1909.

PLANTS can assimilate very little potassium from orthoclase and microcline even when finely powdered, but mica may be used as a source of potassium. Still better results are obtained with a nepheline, as is shown in the following table, giving the relative yields obtained with application of potassium oxide in the form of the minerals named and of potassium chloride.

Plants can avail themselves of about 17 per cent. of the total potassium of mica and 25 per cent. or more of that in the nepheline rock.—E. F. A.

Calcium phosphates: Phase-relationships of the — and bearing upon certain agricultural and biological problems. H. Bassett, jun. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1907, 199, 317.)

As a result of investigations on the three-component system, $\text{CaO}-\text{P}_2\text{O}_5-\text{H}_2\text{O}$, which the author has been carrying out for some time past, it has been possible to construct to scale a solid model of the region of orthophosphates. The greater part of the available surface on this model is occupied by areas corresponding to the five solid phases:— lee ; $\text{CaH}_4\text{P}_2\text{O}_8\cdot\text{H}_2\text{O}$; $\text{CaH}_4\text{P}_2\text{O}_8$; $\text{CaHPO}_4\cdot 2\text{H}_2\text{O}$; and CaHPO_4 . There are, however, a number of areas of very small extent corresponding to the various phosphoric acids as solid phases, and also a number corresponding to several hydrates of three compounds more basic than dicalcium phosphate. These last compounds, perhaps the most interesting of the calcium phosphates, are:—Tricalcium phosphate (which has been obtained in the pure state for the first time), a compound, $[\text{Ca}_3\text{P}_2\text{O}_8]_3$, CaO , (oxygen apatite), and tetracalcium phosphate, $(\text{Ca}_4\text{P}_2\text{O}_8)_3$. Each of these three compounds is stable in contact with a definite, though exceedingly small, range of solutions over a large interval of temperature. Those solutions in equilibrium with tetracalcium phosphate are alkaline to litmus, while those in equilibrium with the other phosphates are acid. Only those solutions in equilibrium with both tetracalcium phosphate and the oxygen apatite are neutral.

The knowledge of the conditions under which the various calcium phosphates can exist in contact with solution throws considerable light on the following important problems:—

(1.) The conditions under which $\text{CaH}_4\text{P}_2\text{O}_8\cdot\text{H}_2\text{O}$; $\text{CaHPO}_4\cdot 2\text{H}_2\text{O}$; and CaHPO_4 , which are occasionally found as minerals, have been formed, and on the nature of the many naturally occurring, so-called tricalcium phosphates.

(2.) The condition in which phosphoric acid is present in the soil. It is probable that that portion of the phosphoric acid of soils which is easily available for plant life is in great measure present in the form of tetracalcium phosphate. The phosphoric acid of Thomas slag is also present as tetracalcium phosphate, and the great success of the slag as a fertiliser is probably in great measure due to this.

Assimilation of phosphoric acid [by plants] from different sources; Influence of calcium carbonate and ammonium sulphate on the —. Prianichnikov. Seventh Int. Congr. Appl. Chem., London, 1909.

ADDITION of calcium carbonate (together with calcium nitrate or other nitrate) to sandy soils produces different effects according to the phosphate employed: With bone-meal, raw phosphate and pure calcium triphosphate, a marked decrease in the yield is observed; with phosphates of iron and aluminium the decrease is less marked; with basic slag, acid phosphate (superphosphate) and dicalcium phosphate, the yield usually remains the same, even if as much as one per cent. (of the weight of the soil) of calcium carbonate is added; in no case was an increase observed. Different results are obtained when ammonium sulphate, which decomposes phosphates, is used instead of nitrate as a source of nitrogen, the best results being obtained when half the calcium nitrate is replaced by ammonium sulphate. If ammonium sulphate is used alone, however, the plants suffer owing to the physiological action of the acid developed, although they are supersaturated with phosphoric acid. If calcium carbonate is now added in small quantity (e.g., 0.25 per cent.) it diminishes the injurious action of the free acid, and the yield is increased; but if more (e.g., 1 per cent.) calcium carbonate is added, the whole of the free sulphuric acid is neutralised, and the plants suffer from phosphoric acid starvation. These results appear not only in the yields of crops obtained, but also in their content of phosphoric acid.

—A. G. L.

Farmyard manure during storage; Losses of manurial constituents in, and the action of preservatives on —. R. A. Berry. Seventh Int. Congr. Appl. Chem., London, 1909.

The object of the investigation was:—

1. To determine the losses of manurial constituents in the storage of different kinds of dung in exposed heaps in a climate with an average rainfall of 41 inches. 2. To compare the losses of dung stored in the open, and under cover, with the results obtained elsewhere. 3. To show the effect of different preservatives of the nitrogen content during the storage of cow dung. The rainfall in that time was 15.1 inches and the mean temperature 39.5°F . The average effect of storage upon the total nitrogen content was to increase the ratio of the insoluble nitrogen by 10 per cent., and to decrease the ammoniacal nitrogen by 10.8 per cent. The proportions of nitrogen in the form of soluble proteins, amides and nitrate, remained practically unaltered. The actual losses sustained by the different forms of nitrogen on the average were total nitrogen 29.6 per cent., insoluble nitrogen 20.4 per cent., ammoniacal nitrogen 80.6 per cent. There was a slight increase in the soluble proteid nitrogen in dungs 1 and 4, and a loss in the others. The dungs are arranged in the order of their losses in total nitrogen. No. 1 suffered least, viz., 13.8 per cent.; No. 5 greatest, viz., 44.0 per cent. The average loss in dry weather was 20.1 per cent.

The effect of storage on the mineral constituents was to cause a slight decrease in the ratio of soluble to total phosphates and potash.

The actual losses on phosphates and potash during storage are shown in the following average per cent. figures:—

Total P_2O_5	12.2	Total K_2O	33.5
Soluble P_2O_5	26.2	Soluble K_2O	38.2

(The total potash includes only the potash soluble in strong hydrochloric acid.)

There was a wide variation in the loss of phosphates in the different kinds of dung. The large proportion of soluble to insoluble phosphates, and the considerable losses which this ingredient may undergo during storage, as shown in this investigation, is significant in the sense that the ratio of $\frac{\text{P}}{\text{N}}$ in the fresh compared with the rotted dung is taken as a basis for calculating the losses of nitrogen on the assumption that the total phosphate content did not alter in the process of rotting. This is, of course,

correct assumption (and borne out in the following experiment) when the dung is stored in water-tight compartments, but not when stored in heaps in the field. The following figures show the per cent. losses by storage mixed dung in the open and under cover from November 25th, 1905, to April 4th, 1906:—

Dung.	Nitrogen.				P ₂ O ₅ total.	P ₂ O ₅ soluble.	K ₂ O total.	K ₂ O soluble.
	Total.	Insoluble.	Soluble Protein.	Ammoniacal.				
Stored in open	28.4	22.9	70.0	77.8	21.2	22.2	28.3	31.17
Stored under cover ..	19.9	15.7	17.0	74.7	6.2	—	3.0	8.7

The losses of nitrogen found in this investigation agree with those found by Wood, Voelcker, Hansen and Günther. The losses, however, sustained by the different kinds of dung are not absolute but only relative to the general conditions of this experiment. The losses in mineral constituents are in general agreement with those found by Verhees. These results emphasise the fact that greater attention should be attached to the considerable losses which the most valuable mineral constituents may undergo the rotting of dung. The preservatives used with cow dung in this experiment were as follows:—

Superphosphate, 25 per cent.	6. Bleaching powder, 1 per cent.
acid salt.	
Kainit, 1 per cent.	7. Formaline, 1 per cent.
Gypsum, 2 per cent.	8. Chloroform, 1 per cent.
Sodium acid sulphate, 5 per cent.	9. Soil on top.
Chalk, 5 per cent.	10. Tightly packed.
" 2.5 per cent.	11. Loosely packed.

The dung was stored in boxes of "haskenized" wood from February 11th to May 11th, 1908, under cover. The average effect on the total nitrogen content was to increase the ratio of insoluble nitrogen by 4.5 per cent., and of the ammoniacal nitrogen by 3.0 per cent., and to decrease the soluble protein nitrogen by 3.5 per cent. The losses of total nitrogen sustained in the different boxes were variable. All were greater than in box 10, with the exception of box 9, which showed no loss. To well consolidate and to cover with a layer of earth is from these results the best condition for storing dung.

Nitrogenous fertilisers; Investigations relative to the use of —, 1898—1907. E. B. Voorhees and J. G. Lipman. Seventh Int. Congr. Appl. Chem., London, 1909.

EXPERIMENTS extending over 10 years were carried out to determine whether, in cases where nitrates and animal manures are used together, destruction of nitrates by nitrifying bacteria involves loss of nitrogen. The results obtained are summarised as follows: There was a marked falling-off in the yields between the first and second rotation, especially in soils not treated with animal manure. Liquid manure was much superior to solid manure as a source of nitrogen. Larger applications of nitrogen were invariably followed by larger yields of this constituent in the crops. Applied in equivalent amounts, nitrate was superior to ammonium sulphate, which last was superior to dried blood as a source of nitrogen. Nitrogen from manure and humus was utilised more thoroughly in presence of nitrate than in its absence. Under certain conditions, nitrates or other readily available nitrogen compounds, may hasten the depletion of the soil nitrogen. Ammonium sulphate and dried blood intensified the development of acidity in the soils. The proportion of nitrogen in the crops was readily affected by the nitrogen treatment and by the character of the crop itself. In the first rotation, the fresh manures produced dry matter relatively somewhat richer in nitrogen than that produced by the leached manures; in the second rotation this result was reversed. The solid and liquid manure, fresh, produced dry matter somewhat richer in nitrogen than did the fresh solid material alone. The smaller application of nitrate, used together with manure, yielded relatively less nitrogen than did the larger application, under the same conditions. From the wide range of the nitrogen content in the crops, it appears that

greater care should be used in supplying nitrogen to cultivated crops. Out of every 100 lb. of nitrogen applied in the form of nitrate, there were recovered in the first rotation, 62.76, and in the second, 61.42; for ammonium sulphate, the figures were 49.51 and 37.01; for dried blood, 47.89 and 32.05. The latter figures are ascribed to

the development of acidity in the soils. For animal manures, the corresponding figures obtained were less than 25 and less than 30 lb. It appears that animal manures have a marked cumulative effect. The corn (maize) crops utilised a smaller proportion of the nitrogen applied than did oats and wheat. Fresh manures were utilised better than leached manures; solid and liquid, fresh or leached, better than the corresponding solid; smaller applications of nitrate to about the same extent as the larger applications; and animal manures used together with the larger applications of nitrate better than when used with the smaller application. Nitrate and ammonium sulphate, when used together with solid manure, leached, were utilised in the order named. The proportion of nitrogen recovered in the crops was 62.09—22.31 per cent.

The following table shows the relative availability of the different materials:—

	First Rotation.	Second Rotation.	Third Rotation.
Sodium nitrate ..	100.0	100.0	100.0
Ammonium sulphate	78.9	60.3	69.7
Dried blood	76.3	52.2	64.4
Solid manure, fresh	32.9	39.0	35.9
Solid and liquid, fresh	50.4	55.6	53.0
Solid manure, leached	33.8	44.0	38.3
Solid and liquid, leached ...	36.6	49.7	43.1

Nitrate and ammonium sulphate showed practically no residual effect, dried blood a slight, and animal manures a very pronounced residual effect. Notwithstanding the annually repeated applications of manure, together with large amounts of nitrate, there is no marked evidence of denitrification. All the soils employed lost considerable quantities of nitrogen.—A. G. L.

Nitrogen manures; The new —. H. von Feilitzen. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1907, 478.)

SINCE 1904 extensive manurial experiments have been made by the Svenska Mosskulturföreningen with the new manures obtained from the atmosphere by means of the electric furnace. The experiments were made partly in pots and in wooden boxes let into the soil, and included also field experiments made at Flahult.

The experiments first described were made with Norwegian calcium nitrate in 1905–8, and included nine different series both in humus sandy soil and in peat soil. The plants grown were oats, potatoes and hemp. In all the experiments the effect of calcium nitrate was at least equal to that of sodium nitrate. In the case of oats the yield of grain in relation to straw was increased more by calcium nitrate than by sodium nitrate. The only drawback with calcium nitrate is its hygroscopicity (compare this J., 1906, 27 and 79). Still more comprehensive experiments were made with calcium cyanamide. Owing to its chemical constitution, its decomposition in the soil gives rise to the production of compounds which may act injuriously on vegetation, and for this reason it is very important to establish by experiments the best modes of employing it with different crops and soils.

Comparative experiments showed that the manure should always be applied some time before sowing the

seed, in order to avoid injury during germination; and as a top dressing it must always be applied very early in order that the plants may not suffer.

In wet seasons calcium cyanamide seems to give better results than under drier conditions.

Calcium cyanamide and dicyandiamide. D. Priamichnikov. Seventh Int. Congr. Appl. Chem., London, 1909.

EXPERIMENTS made with pot cultures in different soils show that calcium cyanamide is but little inferior in manurial value to saltpetre. With buckwheat the following relative yields were obtained:—

Soil.	No nitrogen.	Saltpetre.	Calcium cyanamide.
No. 1.....	8.55	44.8	42.65
No. 2.....	14.96	48.55	40.00
No. 3.....	5.50	33.52	33.53

No difference was as a rule observed whether the calcium cyanamide was added at the time of sowing or a week earlier. In pure sand cultures, calcium cyanamide acts as a poison for all plants and also destroys a second sowing a month or more after the first. When calcium cyanamide is exposed in thin layers to damp air, the loss of nitrogen is considerable, but under the reverse conditions it is very small. Only a part of the nitrogen lost is converted into ammonia.

When dicyandiamide is treated with nitrous acid in the cold, only one-quarter of the nitrogen is liberated, but on warming, one-half of the nitrogen is set free. Hence in the dicyandiamide molecule, there can be but one amino-group, whilst another is formed on heating. This is in agreement with Bamberger's formula,

on heating in acid solution, guanylurea, or dicyandiamidine, $\text{NH}_2(\text{NH})\text{C.NH.CO.NH}_2$, is formed.—E. F. A.

Manures; Catalytic — G. Bertrand. Seventh Int. Congr. Appl. Chem., London, 1909.

EXPERIMENTS show that the addition of manganese to soils acts favourably on a large number of plants, the effect probably being catalytic. Enormous quantities of manganese, 40 per cent., and more, may be used. The action depends on the soil, manganese being without action in some cases. Practically, manganese sulphate and carbonate are used, the quantities being 50 kilos, of the first, and 200–250 kilos, of the second, per hectare; these salts may be mixed with the usual fertilisers. The favourable effects due to manganese are not apparent until the time of harvesting the crops. Other catalytic fertilisers are being studied by other investigators: Zinc acts favourably on the lower plants (*e.g.*, mushrooms), and is capable of increasing the yield of higher plants, but with the latter the toxic dose is not far removed from the optimum dose. Boron promises to give results similar to manganese. Iodine, fluorine, and especially bromine also increase the yield of crops, but their price is against their general application.—A. G. L.

Composition of the sugar beet. Saillard. See XVI.

PATENTS.

Ammonium sulphate; Method of treating — R. England, London. Eng. Pat. 10,781, May, 18, 1908.

From 1 to 5 per cent. of phosphatic material, such as dry, degelatinised bone, calcined bone, or a mineral phosphate, is added to commercial ammonium sulphate, thereby neutralising the product and increasing its manurial value.—O. R.

Nitrogen in liquid farm yard manure; Method of preserving the — C. Ortmann, Schependorf, Germany. Eng. Pat. 26,829, Dec. 10, 1908.

THE fresh manure is first carefully separated from solid matter by filtering through material, such as gravel or straw, placed on gratings in the channels in the cattle house. The liquid then passes along the channels, on the bottoms

of which is placed some substance, such as ground gypsum, to fix the ammonium carbonate. Instead of solid fixing substance, liquids of different specific gravity to the manure may be used, in which case the channels contain dams and the manure is made to pass through the fixing liquid. The volatilisation of ammonia from the liquid manure is prevented by the protection of the surface from the air, which is brought about by damming the manure in the channels, so as to form nearly horizontal surfaces, and covering with oil alone or in conjunction with floating covers. If closed pipes have to be used for conveying the manure, they are kept full and the surface of the liquid covered by a layer of oil. From the channels the manure passes into storage tanks which are provided with floating covers in conjunction with oil and some fixing substance may also be added.—J. H.

Fertilising material; Process of making — J. V. Lowman, Nashville, Tenn. U.S. Pat. 922,494, May 2 1909.

DEFINITE quantities of dolomite and fluorspar are burnt separately, then ground and mixed with a definite quantity of ground phosphate material and potash; water is added to the mixture so as to form a plastic mass, which is then heated.—W. P. S.

Ammonium phosphate; Process of manufacturing stable — N. Caro and T. E. Scheele. Fr. Pat. 397,281, Dec. 9, 1908. Under Int. Conv., Jan. 24, 1908.

AMMONIUM phosphate is manufactured by neutralising crude phosphoric acid, containing several per cent. of free sulphuric acid, with ammonia, and evaporating the solution. The product has the advantage of being stable, non-hygroscopic, and easily distributed as a manure also, it is rich in soluble phosphoric acid (40–45 per cent. and in ammonia (20–25 per cent.).—F. SOEX.

Nitrogen in urine or liquid manure; Process for preserving the — C. Ortmann. Fr. Pat. 397,382, Dec. 1 1908.

See Eng. Pat. 26,829 of 1908; preceding.—T. F. B.

Alkaline salts from blast-furnace tar. Eng. Pat. 16,690 See VII.

XVI.—SUGAR, STARCH, GUM, &c.

Cane sugar [sucrose]; Inversion of — by *invertase* III. C. S. Hudson. J. Amer. Chem. Soc., 1909, 3 655–664. (See this J., 1908, 822, 1076.)

By using a very active invertase solution prepared by the autolytic digestion of yeast at 25° C., it was found possible to effect the rapid inversion of sucrose at 0° C. Under these conditions there was observed first a moderate rapid decrease of rotation during the first few minutes and then a very slow decrease during many hours until finally the ordinary rotatory power of invert sugar was attained. This result is interpreted as being due first to the rapid change of freshly-formed fructose (α -fructose to its stable form (levulose), and secondly to the slow partial change of α -dextrose to β -dextrose; and from the experimental data the rotatory power of α -fructose was calculated to be $[\alpha]_D = +17^\circ$. That this interpretation is correct is confirmed by the fact that the rapid change corresponds to a unimolecular reaction the velocity-coefficient of which is approximately the same as that of the mutarotation of pure crystalline fructose dissolved in the same solution. The inversion of sucrose by invertase may therefore be represented thus:—

The rotation of sucrose ($[\alpha]_D 66^\circ$) is equal to the sum of those of its constituents α -dextrose ($[\alpha]_D 109^\circ$) and α -fructose ($[\alpha]_D 17^\circ$); in a similar manner the rotation of raffinose ($[\alpha]_D 124^\circ$) is equal to the sum of those of its constituent α -melibiose ($[\alpha]_D 171^\circ$) and α -fructose ($[\alpha]_D 17^\circ$). If the free carbonyl group of the aldose and ketose sugars be denoted by the symbol $<$ or $>$, then the constitutions of sucro

id of raffinose may be expressed as α -dextrose \diamond fructose and galactose \triangleleft α -dextrose \diamond α -fructose spectively. The α - and β -forms of dextrose are fermented at very nearly the same rate by brewers' yeast, the former being perhaps decomposed slightly more rapidly than the latter.—A. S.

monomethyl lavulose and its derivatives. Constitution of lavulosediacetone. J. C. Irvine and A. Hynd. Chem. Soc. Proc., 1909, 25, 176—177.

EVULOSEDIAKETONE yields on methylation by the silver iodide reaction a crystalline derivative (*monomethyl avulosediacetone*), melting at 115° , and having $[\alpha]_D^{20} = -136.4^\circ$ in methyl-alcoholic solution. The compound is very easily hydrolysed by dilute acids to give *monomethyl lavulose*, which is apparently the first definite example of a mono-substituted sugar other than the ucosides or the metallic derivatives. The sugar crystallises from ethyl acetate in the pure α -form, which displays utarotation in the downward sense: $[\alpha]_D^{20} = -70.5^\circ \rightarrow -53.1^\circ$. On the other hand, fusion gives an excess of the form, and the reverse optical change ensues on solution, the methyl group in the alkylated ketose is in the position with reference to the reducing group, and, according to this view, the structure of lavulosediacetone:

In addition, it has been shown that the alkylated sugar condenses readily with acetone or with methyl alcohol, and the products thus obtained are interconvertible under suitable conditions. The specific rotations of the various compounds described show that the total optical effect resulting from complete methylation of the sugar molecule is the additive sum of oppositely directed values.

muic acid; Oxidation of — in presence of iron. F. Ferralboschi. Chem. Soc. Proc., 1909, 25, 178.

THE oxidation of muic acid by means of hydrogen peroxide in presence of iron has been investigated. The principal product is a strongly reducing acid, which appears to be a *hydroxymuic acid*. It may also be regarded as a ditonic acid, namely, *dihydroxydiketonidipic acid*. Its *hydrazone* has been prepared. Parallel experiments on the oxidation of saccharic acid gave analogous results, the products obtained are not identical with those derived from muic acid.

beet sugar industry of the United States. A. H. Bryan. Seventh Int. Congr. Appl. Chem., London, 1909.

WHITE sugar is made direct from beets in the United States, no raw sugar being made to be sent to the refinery. The osmose process for recovery of sugar from molasses is being rapidly replaced by the Steffen lime process. Improvements have been made in this process in the direction of a more uniform saccharate cake of higher purity. The waste materials of the factory are becoming of greater commercial importance, *viz.*, pulp for cattle feeding, molasses for cattle food, and alcohol. But no attempts have yet been made to utilise the lime cake except in a few cases as a fertiliser, the waste water in factories, etc. The home production of beet seed is on the increase.

Java sugar industry; Review of the conditions, progress, and future outlook of the —. Th. Brooks. Seventh Int. Congr. Appl. Chem., London, 1909.

IN 1906–7 the total production of the island was 1,427,673 tons, produced by 186 factories, and this year's crop is estimated at 1,350,000 tons from 170 factories. Of the 186 factories, 74 were owned by Cubans, 36 by Americans, and 76 by British, Spanish, and other foreign interests. During the last years there have been many improvements in the process, in milling especially, the per cent. of sugar obtained averaging 10–16 per cent. weight of cane ground. Chemical control was carried out by few factories in the early eighties, but now many

factories are under this control. On the agricultural side the greatest advancement is yet to come. No attention to scientific agriculture has been paid. The soils being normally very rich and considerable land being available, the necessity for scientific methods of agriculture was not recognised, and as a soil became depleted the cane was grown in fresh soil. The production of sugar in the island can be increased (1) by improving the equipment and methods of manufacture of a majority of factories; (2) by improved methods of agriculture to increase the yield; (3) by extension of cane cultivation into undeveloped lands. The Agricultural Experiment Station is doing good work. Labour is a difficult problem in the island. The average cost of manufacture might be given as 2.25 cents, though some factories operate at a much lower figure.

Cane sugar industry in the Hawaiian Islands. N. Decr. Seventh Int. Congr. Appl. Chem., London, 1909.

IN 1882 the output of the islands was only 54,000 tons, whilst in 1908, 521,123 tons were exported. This increase was brought about by a reciprocity treaty with the United States, and the possibility of irrigation in the arid districts. Two main varieties of cane are planted: Lahaina under irrigation and Yellow Caledonia under natural rainfall. The islands of Oahu, Maui, and Kauai are all irrigated. The yield under irrigation is about 12,000 pounds per acre, under natural rainfall, 5000 to 8000 pounds. Fertilisers are used to some extent. The average production per factory in 1908 was 11,000 tons of 2000 pounds. The mills are mostly 11 rollers; 95 to 98% test sugar is the product, and goes mostly to New York and San Francisco.

Cane sugar industry of Peru. F. Zerbán. Seventh Int. Congr. Appl. Chem., London, 1909.

SUGAR cane is grown mostly in the valleys along the coast region under irrigation. There are about fifty estates producing sugar, with a maximum area of 8000 acres under cultivation. About 150,000 tons of sugar are produced; of this about 120,000 tons are exported, mainly to England and Chili. The factories are mostly old and not equipped with recent improvements. The average yield of cane is between 35 and 45 tons per acre.

Sugar cane seedlings in Java. J. D. Kobus. Seventh Int. Congr. Appl. Chem., London, 1909.

AFTER a short historical review, the author describes the progress made in Java since the first seedling canes were raised in 1887 by F. Soltwedel. He mentions the improvements made by Moquette, the researches about cane flowers by Wakker, the cross fertilising experiments made by Bonricus, and those made on a large scale by himself. By crossing the valuable Cheribon cane (which, however, was liable to several diseases, that spread through Java in the late years of the nineteenth century), with other varieties immune against these diseases, the Java experimenters succeeded in raising several cane varieties with superior qualities. The methods now in use for the raising of new varieties are successively described. The selection of the parents, the choice of the male and female plants, the way in which the cross fertilising is effected, the sowing out of the cane seeds, the manipulation of the young seedlings and the selection of the mature ones are all referred to. The cultivation of seedling canes has saved several factories in Java from ruin and enabled others to pay high dividends in recent years. In fact, in the last 25 years, the output per acre has nearly doubled, and since the new varieties can be cultivated with success on soils where the older ones proved a failure, the area under canes also nearly doubled. Thus the cultivation of seedling canes has contributed in large measure to the increase of the sugar production in Java from 350,000 tons in 1885 to over 1,200,000 tons in 1908.

Sugar beet; Composition of the —. E. Saillard. Seventh Int. Congr. Appl. Chem., London, 1909.

THE sugar beet (leaves and root) contains more nitrogen, per 100 kilos. of sugar produced, in dry than in wet years. Of varieties improved by selective cultivation,

those with most sugar contain in their ash less sodium oxide and more phosphoric acid and lime than do poorer beets. Conversely of a number of roots of one variety, those with least sodium oxide in their ash contain most sugar. The roots contain most nitrogen in dry years; chlorides pass almost entirely into the leaves. With beets containing 15.7 per cent. of sugar, analysis of the entire plant gave the following results expressed per 100 kilos. of sugar produced: Nitrogen, 2.4–2.8; phosphoric acid, 0.6–0.97; potassium oxide, 3.2–3.6; or in all about 8 kilos. of (potassium oxide, sodium oxide, magnesium oxide, calcium oxide, phosphorus pentoxide). This figure is below that of 10.7 kilos. obtained as the normal about 30 years ago, but even lower figures have been obtained in Bohemia, Austria, and Belgium for beets still richer in sugar.—E. F. A.

Beetroot: Determination of crystallisable sugar in the — H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909. (Internat. Comm. for Unification of Methods of Sugar Analysis.)

THE author makes the following propositions:—(1). The direct determination of sugar in the beetroot, in whatever form it may be, shall be made exclusively by means of the aqueous method of Pellet as described by the author since 1888, under the title of instantaneous diffusion in the cold, and according to the well-known directions for its use; (2). The pulp to be analysed in the cold shall be produced by the special apparatus of H. Pellet and Lomont, Herles, and Mastain and Delfosse and others according as the material consists of the beetroot, chips, coarse pulp, raspings, chopped beet or pieces. Also, for the application of Pellet's method use may be made of various special apparatus, particularly those of Sachs, Le Docteur, etc.; (3). The hot aqueous method shall serve solely as a method of control of the results of the cold method of aqueous digestion in case there is any doubt as to the division of the pulp; (4). Alcohol shall no longer be used for the direct determination of sugar in the beetroot, this solvent having no advantage over water and having, on the contrary, many disadvantages.

—L. J. DE W.

Sugar beets: Optically active non-sugar constituents of — which influence the polarisation results. F. Strohmer and O. Fallada. Seventh Int. Congr. Appl. Chem., London, 1909.

WHEN beet-pulp is extracted for analysis by the hot water method (100° C.) it is frequently found that the sugar value obtained by direct polarisation is more or less in excess of that obtained by Clerget's method. In some cases this excess may amount to 3 per cent. of sugar on the juice. The error is due to the extraction of dextro-rotatory pectic substances by the hot water; these substances are precipitable by basic lead acetate, but for many reasons the quantity of this reagent must be restricted, so that in many cases it is insufficient. The quantity of pectic substances extracted varies, also, with the composition of the beet and, consequently, according to season, locality, and conditions of cultivation. The procedure adopted for the extraction of the sugar in industrial analyses must therefore be to a certain extent elastic and its results controlled by some exact method, such as alcoholic extraction or Clerget's method of polarisation after inversion. The quantity of pectic matters extracted by hot water increases with the temperature, and is only small at 50° C. Still, the cold water extraction methods are preferable and the error introduced by the presence of minute air bubbles in the finely-rasped pulp may be avoided by adopting the means prescribed by Sachs and Le Docteur.—J. F. B.

Beetroots: Influence of pectic matters on the polarisation of — extracted by Zeheye's method (saline digestion) and that of Strohmer and Fallada. H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909.

THE beetroot contains pectic matters which have a dextro-rotatory power from 3 to 3.3 times as great as that of sugar. When extracted with water, these pectic matters may show a polarisation equivalent to 6.3 per cent. of

sugar on the beet, in extreme cases. They are capable of being completely precipitated by basic lead acetate if the latter is used in sufficient quantity. In Zeheye's method, when salt is added to the digestion liquid, the excess of the salt decomposes the lead precipitate, the pectic matters are re-liberated and still exist in the juice making the apparent sugar-content too high. An aqueous extract of beets polarised without the use of basic lead acetate will contain these pectic matters. In the process of inversion of the sugar the rotatory power of the pectic matters remains unchanged. Consequently the levorotation of the inverted juice is lower than that of pure invert sugar. If the direct polarisation be determined on juice clarified with lead acetate and the inverted polarisation on juice inverted without clarification, the calculated quantity of sugar is too low. If both observations be made on the same juice, whether clarified or not, the correct quantity of sugar is obtained. With this precaution, all aqueous extraction methods, including those of Strohmer and Fallada (without lead) and of Zeheye (with salt) will give correct results. Clerget's method, properly applied, gives the correct quantity of crystallisable sugar and of raffinose if present. There are no such things as "abnormal" beets and "unknown" losses. Beets may contain more or less sugar, raffinose, reducing sugars and pectic matters, but there is nothing "abnormal" about them, and the last may be eliminated by basic lead acetate. Certain of the losses in the sugar factory may be difficult or impossible to determine but they are all known.—J. F. B.

Cane sugar factories: Losses in — H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909. Internat. Sugar J., 1909, 11, 294–300.

LOSSES in cane sugar factories occur (1), during extraction of the juice; (2), during concentration of the juice; (3), in scums, filter-press cake, etc.; (4), in condenser water, and by entrainment; (5), as mechanical and other losses. The diversity of the methods of extraction causes considerable variations in the working losses, these being usually from 0.5 to 2.5 per cent. on the weight of the cane. In modern factories where milling alone is adopted the loss is generally kept at an average of 1 per cent. on the weight of the canes. With diffusion of the mill bagasse the loss is reduced to 0.6 and even to 0.3 per cent. under favourable conditions. By direct diffusion of the shield cane the loss amounts to 0.6 per cent. Loss during defecation and concentration are largely affected by the nature and amount of the purifying agent employed. The quantity of scums obtained varies between 0.8 and 1.5 per 100 parts of cane and they contain from 6 to 10 per cent. of sugar. This loss, with that arising from saturated filter bags and cloths, amounts to 0.1 to 0.3 per 100 parts of cane. With the carbonatation process and washing the filter-press cakes the loss may be reduced to from 0.05 to 0.1 per 100 parts of canes. There are besides these, inversion losses and those arising from entrainment during evaporation, as also overweight and handling losses, amounting with the bagasse to already mentioned, to a total of 1.5 per cent. on the weight of canes. The author considers the following precautions to be necessary if the true sucrose content of the canes is to be arrived at:—(1). The sucrose should always be determined by Clerget's method. (2). The quantity of juices, syrups, and exhausted molasses should be based on the actual composition of these products as distinct from their apparent composition. (3). All sugars, both pure and impure, should be analysed by Clerget's method. He further states that the loss of crystallisable sugar during manufacture is not nearly so large as was formerly supposed, when the large proportion of reducing sugar contained in the molasses was attributed to inversion.—J. A.

Sugar samples: Drying of raw — and a method of avoiding it. V. Stanek. Seventh Int. Cong. of Appl. Chem., London, 1909.

RAW sugar samples are usually received in small boxes, and on being kept for some time in a warm room there is sufficient drying up to affect the polarisation. Numerous careful tests showed a total loss, calculated

sugar, in 32 days of 0.106 to 1.144 per cent. Wrapping the boxes in a double envelope of stout paper did not prevent drying. Stopped glass bottles are effective at clumsy, particularly for sending samples by post. The author has found a suitable material for hermetically sealing the boxes in ordinary caoutchouc plaster ("lenko-last"). Lenkoplast is sold in strips of various widths and lengths of 10 metres wound on spools. The cotton cloth which serves as support is pasted over with a sticky, hygroscopic layer consisting of zinc oxide, caoutchouc, and a non-drying solvent. With a slight pressure the material adheres firmly to the tin and may be easily loosened again when required. The author prefers strips 1½ cm. wide. If the sample is too cold, the lenko-last is warmed by passing it through a flame.—L. J. DE W.

juices of the last diffusers [Sugar]; Purity of the — compared with that of the diffusion juice. Regularity of diffusion. H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909.

It has often been shown that the weak juices from the last diffusers yield crystallisable sugar after purification. Hence, it is advisable to carry the extraction of the sugar as far as possible, and even to return the waters (preferably after a preliminary purification) to the battery. With regard to the purity of the juices from the last diffusers, the author points out that if the juices are filtered, prior analysis (since suspended matter ought not to be included in the determination), and if correction is made for the saline matter in the water used in the battery, it will be found that the purity of such juices does not differ much from that of the juices withdrawn from the head of the battery; in fact the purity of the juice does not vary much from one diffuser to another. Variation in the sugar content of the beetroot has very little influence on the purity of the diffusion juice owing to admixture of different juices. The daily average purity of the diffusion juice varies very little; the weekly average purity also varies very little and does not decrease sensibly even at the end of the campaign if this is not of very long duration. If, however, the campaign is long continued, and the roots have been affected by cold weather during storage, the purity of the diffusion juice slowly decreases.—L. E.

beetroot and cane sugar works; Relation between apparent and real purity in products of —. H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909.

beetroot sugar works.—(1). The study of the relation between the apparent and real purity of pressed juice from beetroot pulp is of no interest. These juices, deprived of air by the action of a vacuum, have necessarily a slightly lower purity than diffusion juice. (2). The apparent purity of diffusion juice is generally slightly lower than the real purity when drawn off at a low temperature, and freed from air, pulp and suspended matters. (3). The difference may be higher when the juice is drawn at a high temperature owing to the smaller proportion of agglutinated organic impurities. (4). When the proportion of "other organic matter" to mineral matters is relatively high, especially when very pure water is used for diffusion, the apparent purity of diffusion juice may be equal or even slightly higher than the real purity when derived from sound beets from silos, though the conditions are changed if the beetroots have suffered deterioration. (5). The apparent purity of carbonated and saturated juice ready for boiling is always lower than the real purity. This difference diminishes *à passu* as the apparent purity increases. Any variations between the two purities from one year to another, under identical conditions of working, are never large nor abrupt. This is clearly shown in the tables by Sachs on the chemical control of the Belgian and Dutch sugar works. The author's results agree with those of Sachs starting from beetroots of 30 years ago with 8 to 9 per cent. of sugar to those containing from 18 to 22 per cent., and it is possible to draw up a table giving the average purity of carbonated juice for beetroots of from 13 to 22 per cent. of sugar which would be fairly correct in most cases of ordinary work. Consequently, using Weisberg's table it is possible to give the real purity with close

approximation when the apparent purity is known. (6). Owing to the presence of raffinose, the real purity calculated from the polarisation by inversion by Herzfeld's formula will be slightly lowered and will approach the apparent purity. (7). In beetroot molasses the difference between the apparent and real purity is greater than in syrups and runnings and may amount to 2 or 3, the difference increasing with increase in ash arising from the use of impure water or the addition of sodium bisulphite or carbonate, or when calcium salts have been allowed to form. It is rare to find a difference in the purities greater than 4 and abrupt variations are greatly minimised by the returned syrups. (8). As in the case of juices, molasses analysed by the Clerget inversion process give a polarisation always lower than the direct polarisation; the difference varies from 0.8 to 2 per cent., but may reach 3 per cent. even when no particular method of extraction of sugar has led to concentration of raffinose in the residues. Here also the formula of Herzfeld should be adopted, taking account of raffinose. The real purity would be lowered and would thus approach very closely the apparent purity. (9). The real purities refer to those obtained by desiccation under suitable conditions and where, normally, large quantities of alkali are not present. (10). For intermediate products the difference in the two purities is greater or less as the product approaches molasses in purity. In any case comparable results necessitate working under the same conditions and with instruments perfectly controlled and corrected. When the accuracy of the instruments is not certain, the various products should be all brought to the same density so as to obtain comparative results. (11). It is not advisable to calculate the apparent purity of molasses from the specific gravity determined with the aid of a flask. (12). For the control of beetroot sugar works, the apparent purity is amply sufficient to follow the working and is easily determined.

Cane sugar works.—(1). The apparent purity of cane juice differs notably from the real purity. (2). This difference is due to reducing sugars and organic matters and ash, the latter largely influencing the Brix determination. (3). The reducing sugars affect the results more when levulose predominates over dextrose. (4). A quantity of 0.7 to 0.9 of reducing sugars per 100 c.c., representing 5 to 7 per cent. on the sugar, alters the sugar by 0.3 to 0.4. (5). The purity may thus be increased by 2 to 2.5 by the presence of reducing sugars in sensible quantity. (6). At times the effect of reducing sugar is *nil* if it is in small quantity and comes from ripe canes, or the effect may be even reversed, less sugar being found by inversion than directly. (7). By desiccation 2 degrees of purity are gained; the total difference between apparent purity and real purity by the Clerget method and desiccation may thus reach 5. (8). The composition of the juice is quite different as given by the apparent and by the real analysis. (9). It is chiefly the organic matters which are greatly lessened. (10). The apparent purity of cane molasses may be as low as 20 to 22 when there is much reducing sugar; very often it lies between 30 and 40. (11). The real purity then increases very much, first owing to the reducing sugar which may equal 60 to 120 per cent. of the crystallisable sugar and secondly by the dry matters which may reduce the apparent Brix by 8 to 10 degrees. Thus there are real purities of 12 to 43 with apparent purities of 27 to 30, and 48 to 50 corresponding to 37 to 40. (12). The results cannot be given so precisely as for the beetroot, the quality of the cane being excessively variable. During the same day's work there may be a minimum of 76.5 and a maximum of 85 of purity, and for the same season 75 and 90 respectively. Taking the various sugar works of the world, canes are worked having 9 to 12 per cent. of sugar, of 68 to 75 of purity and 12 to 20 of reducing sugars per 100 of sugar; others have constantly cane of 13 to 16 and even 17 per cent. of sugar, 1 to 3 of dextrose per cent. of sugar and a purity of 87 to 93, so that even approximate relations cannot be given between apparent and real purity. In view of the considerable number of operations necessary for the analytical control of the works, increased by the necessity of determining the reducing sugar, it is advisable to plot results for the different products graphically, to show

the apparent and real purity. (12). As for beetroot molasses, so also for cane molasses the dense and emulsified condition of cane molasses and the difficulty of removing the contained air, renders the specific gravity method useless for determining the apparent purity. The same product may give from 74 to 80° or 90° Brix. By dilution a constant result is attained.—L. J. DE W.

Sugar house products; Influence of concentration on the determination of the apparent degrees Brix of impure

— H. Pellet and C. Fribourg. Seventh Int. Congr. Appl. Chem., London, 1909.

IN the chemical control of sugar house work the determination of the quotient of purity of the various products necessitates a rapid estimation of the total solids, generally expressed as "degrees Brix" and determined by the density. The relation existing between the real quotient of purity and the apparent quotient calculated in this way should be controlled from time to time. It has long been known that the greater the dilution of the solution of molasses which is used for the determination of the density, the higher is the apparent degree Brix when calculated back to the original molasses. In establishing the relation between the apparent purity and the real purity, some constant dilution of the solution used for the density determination should be selected and adhered to, for instance 3 or 6 times the normal weight in 300 c.c., and the same solution would serve for the determination of the sugar. In this way the factor of dilution would be compensated in calculating the results. When small quantities of water are added to molasses, the influence of the dilution on the degree Brix is large; it is large also when the proportion of molasses is small. For the intermediate concentrations, between 24 and 97 grms. per 300 c.c., there is only a difference of 0.5° Brix over the whole range. In the case of concentrated vinasses deprived of nearly the whole of their sugar (e.g. by the strontia process), the influence of dilution on the degrees Brix is very much greater than in the case of molasses. Cane molasses show the same relationships as beet molasses, and provided the same weight of molasses be always taken, the slight differences in dilution due to variations in the composition of the original substance have no influence. The variation is indeed so slight that the results of different factories, employing standard saccharimeters and working with solutions ranging from 78 to 120 grms. of molasses per 300 c.c., may be compared with one another. The dilution of the molasses for the determination of the density possesses the great advantage of enabling the air to be expelled from the solution. Molasses, especially cane molasses, retain the air very obstinately in their concentrated form and serious errors may thereby arise.

—J. F. B.

Hydrometer readings [Sugar]; Influence of surface tension on — B. Delachanal. Seventh Int. Congr. Appl. Chem., London, 1909.

FROM experiments on the surface tensions of solutions of pure sugar and molasses, the author concludes that the Brix hydrometer, standardised by means of solutions of pure sugar, gives values for the apparent purity which are sufficiently accurate in the case of syrups of high purity, but which may err to the extent of more than 1 per cent. in the cases of mother syrups and molasses.—L. E.

Sugar factory and refinery products; Determination of the dry substance in — H. Pellet. Seventh Int. Congr. Appl. Chem., London, 1909.

THE procedure to be followed in order to obtain satisfactory results in the determination of the dry substance is thus described:—A metal capsule of at least 80 mm. diameter is required, of small height, having a lid with a curved flap, a thin stirring rod and a recess of the shape of a shell reserved in the interior for weighing out the substance to be dried. A measured quantity of powdered pumice, sand, or bibulous paper, always the same for capsules of the same size, and amounting to 10, 12, 15 or 20 grms. for capsules of 90 mm., should be taken. A quantity of the substance is weighed out into the shell-shaped recess, equivalent in dry substance to not more

than 10 per cent. of the weight of pumice employed. Ten c.c. of boiling water are then added to dissolve the substance and distribute it equally throughout the pumice. The capsule is placed in the oven, previously heated to 105°–106° C., and maintained at a constant temperature. The first weighing is made after 3 or 4 hours, and weighing are repeated at intervals of half an hour until two are concordant within 3–4 mgrms.; when everything is properly prepared the second and third weighings should agree. The capsules should be cooled in thoroughly efficient desiccators and not left too long before weighing; they should be weighed with their covers, and as rapidly as possible, the weights being previously placed on the pan. Acid substances, such as cane products, should be neutralised with a drop of ammonia before drying. Substances which are exceptionally alkaline should be neutralised, or nearly so. In the case of liquids, the substance should never be measured, only weighed. All determinations should be made in duplicate together with a blank experiment with pure sugar, dissolved and dried in the same manner as the test substance. In special cases the substance may be dried in a current of dry air at a temperature below 100° C.—J. F. B.

Ash in sugar and syrups; Determination of — by the estimation of the electrical conductivity. H. Main. Seventh Int. Congr. Appl. Chem., London, 1909.

THE method described gives a simple, rapid, and accurate means of estimating the ash in sugar house samples. For practical purposes it may be considered that sugar in solution is a non-electrolyte, and that the conductivity of impure sugar solutions is due to the organic and inorganic salts present. If in a series of samples, solutions of the same concentration are made, the resistances of the solutions are inversely proportional to the amount of salts present. The resistances are measured by Kohlrausch's method of using an alternating current between platinum electrodes. The apparatus required consists of:—1. Accumulator of two cells. 2. Induction coil giving a clear high note. 3. Bridge.—A resistance of 200 ohms is placed in each of two of the proportional arms, while the resistance to be measured and a resistance box occupy the two other arms. 4. Resistance cell.—This should be "continuous" in the same sense as the "continuous tube" for the polariscope. The electrodes are of stout platinum foil attached to wires fused into glass tubes which are filled with mercury for making connection with the bridge. The electrodes should be platinised as directed by Kohlrausch. The cell is placed in a water bath kept at a constant temperature, and is provided with an oblong cover through which pass the two tubes of the electrode and a small funnel. The lower end of the cell is continued into a tube passing through a rubber cork in the bottom of the water bath. The tube is closed by means of a piece of india-rubber tubing and a spring clip. The "cell constant" of the cell used is about 0.38, and is determined by using a $N/100$ solution of potassium chloride. 5. Resistance box with resistances of 1, 2, 3, 4, 10, 20, etc. to 4000 ohms. 6. Telephone.

The temperature of the water bath and solutions when tested must be kept at 20° C. The cell is rinsed out about three times with the solution and then filled always to the same height. On passing the current from the coil a loud note is heard in the telephone. When the resistance in the box is adjusted to equal that of the solution in the cell, the sound decreases to a minimum. Although the sugar in the solutions may be regarded as non-conducting, variations in the amount of sugar in a solution affect the conductivity of the salts present. The disturbing influence of differences in the amount of sugar present can be removed by always making the solutions of about the same density. Taking a series of sugars of about the same quality containing from 2 to 5 per cent. of ash, 5 grms. of each are dissolved in distilled water, made up to 100 c.c., and the resistances of the solutions determined at 20° C. Then the resistances expressed in ohms multiplied by the percentage of ash, as determined gravimetrically in the usual manner, gives approximately a constant product.

Ohms \times per cent. ash = Constant.

having found the mean constant by a short series of experiments, the figure so found serves for the determination of the ash in other samples of similar sugars in the resistance of their solutions is determined in same manner in the same cell.

Constant ÷ ohms = per cent. ash.

The amount of ash so ascertained agrees well within limits of permissible error with that found gravimetrically. In the case of molasses the samples are diluted to B., and 2 grms. are taken and made up to 100 c.c. the constant determined as in the case of the sugars. Instead of using the same weight of all samples of sugars, syrups and expecting to get a simple method of relating the ash from the resistance of the solutions, if it is taken to bring the conditions of series of each into harmony, the ratio between resistance and the amount of ash may be determined in a limited number of samples, and the factor so obtained employed for the estimation of ash in further samples of approximately the same composition. Once the conditions and constants are ascertained, the estimation of the ash can be far more easily, accurately and quickly made than by the gravimetric method. Very little experience is required to get its value within the limits of the gravimetric method, when the apparatus is in order an estimation can be made in less than ten minutes.

ert sugar; Influence of clarification on the valuation of raw sugars and molasses containing —. H. C. Prinsen Geerligs. Seventh Int. Congr. Appl. Chem., London, 1909. Internat. Sugar J., 1909, 11, 276—81.

The author recognises that basic lead acetate, both in the state and in solution, precipitates a part of the chemically active constituents from raw cane sugars and molasses, more particularly if it is used in excess. In the present state of our knowledge, however, he advises the continued use of this reagent for the clarification of such solutions for the purpose of their polarimetric estimation, with the precaution that only the minimum amount necessary for obtaining a distinct reading be added. He further suggests that solutions of sugars, molasses, etc., in which it is desired to determine the *ert sugar* (dextrose, or reducing sugars), should, if alkaline (to phenolphthalein), be neutralised with acetic acid and the neutral or acid solution be clarified with lead subacetate, the excess of the lead salt being removed in the filtrate by the addition of sodium carbonate, sodium sulphate, or other suitable precipitant.—J. A.

ification with basic lead acetate solution; Influence of —, on the valuation of sugar products and the relation between the amount of lead added and that precipitated. L. Eynon. Seventh Int. Congr. Appl. Chem., London, 1909.

EXPERIMENTS have been made to determine the influence of increasing quantities of basic lead acetate solution, of its own lead-content, on (a) the direct polarisation, (b) the sucrose-content determined by Clerget's method, and (c) the reducing sugar-content, of samples of jaggery and Cuban molasses. The lead-contents of the clarified solutions were also determined, the weights and percentages of lead precipitated being calculated therefrom. *Jaggery sugar:* 52.00 grms. of the sugar were dissolved in water, treated with a known volume of basic lead acetate solution (containing 210.36 grms. of lead per c.c.), and 1 c.c. of alumina cream, the whole being made up to 200 c.c. and filtered: the filtrate was used for the above-mentioned determinations. Sixteen such experiments were made, the quantities of lead solution used, ranging from 2 to 50 c.c. (8 c.c. were sufficient for binary analysis). It was found that with increasing quantities of the lead solution, the direct polarisation decreased, the inversion polarisation decreased (i.e., became *levo-rotatory*), and the reducing sugar-content increased. The figures for the sucrose-content showed increase, but this was small in comparison with the

other variations. The following table, giving details of experiments, 3, 4, 12, and 16, illustrates these results:—

Volume of lead solution added.	Direct polarisation.	Sucrose per cent. (Clerget).	Wt. of lead in ppt. from 52 grms. of sample.	Percentage of lead pptd.	Reducing sugar per cent.*	
3	6 c.c.	73.2	76.0	grms. 1.1542	91	9.7
4	8 c.c.	73.4	76.1	1.4570	87	9.6
12	26 c.c.	74.0	76.3	3.2978	60	9.1
16	50 c.c.	75.1	76.5	4.7364	45	8.5

* The percentage of reducing sugar as found from the unclarified solution was 10.2.

These results are in harmony with Prinsen-Geerligs' statement that levulose is partially precipitated (and also dextrose, but to a much less extent) with the non-sugar by basic lead acetate. Special experiments showed that, of the increase in the value for sucrose—0.5°—about 0.1° to 0.2° was due to the influence of the lead left in solution on the rotation of the sucrose. Further experiment showed that the remaining increase of 0.3 to 0.4° was not due to optical alteration of the non-sugar during inversion, and it appears, therefore, that this increase was due to the increased volume of the lead precipitate. The weight of lead is an approximate measure of the weight of the precipitate containing it. The table shows that the amount of precipitate obtained with 6.8 c.c. of lead solution was comparatively small, and that the precipitate obtained with, say, 8 c.c. of lead solution (the amount required for clarification in an ordinary analysis) could not cause an error of more than 0.1° to 0.2°.

Cuban molasses.—26.00 grms. of sugar were weighed out in each experiment, the clarified solution being made up to 200 c.c. Eleven experiments were made; the following table gives the details of experiments 2 and 11:—

	Volume of lead solution added.	Direct polarisation × 2.	Sucrose per cent. (Clerget).	Wt. of lead in ppt. from 26 grms. of sample.	Percentage of lead pptd.	Reducing sugar per cent.†
2	15 c.c.	32.3°	39.25	grms. 2.3746	75	12.5
11	60 c.c.	35.9°	40.0	5.7300	45	10.5

† The percentage of reducing sugar as found from the unclarified solution was 13.9.

Cane molasses; Analysis of —. A. R. Ling and G. McLaren. Seventh Int. Congr. Appl. Chem., London, 1909.

THE authors state that the observations of Eynon (see preceding abstract) that defecation with basic lead acetate has little influence on the sucrose percentage as determined by Clerget's method, which is therefore a value of considerable accuracy, is borne out by the close agreement which they find between the percentage of sucrose as determined by Clerget's method, and by the copper reduction method (volumetrically) from the difference in the reducing power before and after inversion (see Ling and Rendle, this J., 1905, 753). The maximum difference would appear to be 3 per cent., reckoned on 100 parts of sucrose; but usually it is much less than this. Considering the impure nature of the commercial product in question, large differences might be expected, and bearing in mind the fact that in principle the two methods are quite distinct, the agreement must be regarded as satisfactory. The Clerget results are generally the higher. This is doubtless due to the volume occupied by the lead precipitate which Eynon shows to be of some influence.

Bagasse; Analysis of —. D. L. Davoll, jun. Seventh Int. Congr. Appl. Chem., London, 1909.

A COMPARISON of the alcoholic and the aqueous extraction methods for the determination of sugar and fibre in bagasse. It is found that by the alcoholic method more sugar is extracted from bagasse than by Gerlig's aqueous method, provided the bagasse is cut up fine enough:

also that the fibre determination gives a lower figure by this method when both determinations of sugar and fibre are made in one operation. In using the alcohol method the results for ash and protein are higher than with the aqueous method. It is shown that the reason the alcoholic extraction does not remove the sugar from a coarse bagasse is due either to the inefficiency of the solvent or to the precipitation of optically active non-sugars, but that it is not due to the passage of the alcohol through the bagasse in set channels, since continual extraction ultimately removes all the sugar. The preliminary study is begun upon the method of sampling and sub-sampling bagasse at the mill, showing where the errors ordinarily made, occur. It is also shown that formaldehyde cannot be depended upon to preserve bagasse.

Sugar and corn [maize] syrup (starch glucos) as raw materials for the confectionery and preserves industries.

L. K. Bosceley. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author endeavours to bring to the notice of sugar refiners and corn syrup manufacturers, the requirements of confectioners and jam and marmalade makers, as regards the properties of sugar and corn syrup as raw materials. Tests are given, to which such sugars, etc., would be subjected in jam and confectionery factories before they could be passed as suitable, and it is pointed out that the ordinary tests by polarimeter, cupric reducing power, and refractometer are useless to confectioners, as all sugars used are of the highly refined type, polarising over 99.9 per cent. of sugar. The first test used consists in heating the sugar with water and potassium bitartrate to 163° C. Great differences are found to exist in highly refined types of sugar when subjected to this test. Sugars polarising over 99.9 per cent. sugar, and, indeed, showing practically no difference under ordinary analytical tests, will, in some cases, turn dark brown, and in others remain lemon yellow or nearly white. The author then suggests possible reasons for these results, pointing out that the formation of invert sugar, by the potassium bitartrate does not, under the conditions employed in the test, affect the colour. The suggestions are:—(a) Slight alkalinity of the sugar. (b) Presence of minute traces of nitrates causing oxidation. (c) Liberation of an organic acid at 163° C. or slightly under. (d) Preparation of the sugar in certain refineries where the water supply contains a high amount of organic impurity. (e) The presence of sulphates in small amounts. The author's experiments point to the last named as the principal cause of the darkening effect.

The second test to which highly refined sugars would be subjected by manufacturing confectioners consists in the ability of these sugars to grow crystals on fondants, or other confectionery. The confectionery is packed in sieves in a galvanised iron tank, and covered with a 72.75 per cent. solution of the sugar to be tested. The whole is then allowed to stand for three hours, after which the sugar solution is run off. Widely marked differences will be shown in the case of this test, even by highly refined sugars sent out by various well-known firms, and, although the sugars may be of precisely similar grades, some will give a fine brilliant well-marked crystal, while others give nothing more than a coating destitute of any sparkling or well-defined crystals. The author believes, as a result of experiments made by himself and others, that the power of crystallisation exhibited by certain highly refined sugars when compared with others of a similar grade, must be due to some purely physical character, and not to a chemical one. A granulated sugar which exhibited excellent powers of crystallisation was disintegrated and sifted through fine silk, thereby being reduced to a very fine powder, and it was found, on again applying the above test, that its power of crystallisation was very much impaired. It would appear then that the ability of a solution of refined sugar to withstand a temperature of 163° C. without darkening, and its crystallising power, constitute two of the most searching tests which can be applied to it, and, as confectionery sells almost entirely according to its appearance, both tests are of the

greatest moment to the manufacturing confectioner, who is one of the refiners' largest customers. The author has also given some details concerning confectioners' syrup the bleaching of sugars and corn syrup (starch glucos) with ultramarine, and the presence of sulphurous acid and sulphites in corn syrup.

Dextrose, levulose, and maltose: Solution densities of—
A. K. Ling, L. Eynon, and J. H. Lane. Seventh Int. Congr. Appl. Chem., London, 1909.

THE authors have prepared the three sugars above named in a state of high purity, the criterion of the latter being constancy of specific rotatory power under standard conditions of temperature and concentration. The following values were obtained with the final products, expressed in each case on the anhydrous sugars:—Dextrose $[\alpha]_D^{17} + 52.72^\circ$ ($c=10$), levulose $[\alpha]_D^{18.5} = -93.83^\circ$ ($c=10$), maltose $[\alpha]_D^{17.5} = +137.79^\circ$ ($c=5.7$). The specific gravities of solutions of these preparations, varying in concentrations from $c=1$ to $c=24$, have been determined in duplicate. The results practically confirm those of Brown, Morris, and Millar (Chem. Soc. Trans., 1897, 71, 7, 276; this J., 1897, 166), and the excuse for publishing them rests mainly on the fact that the purity of the various sugars employed is beyond all question, and that a considerably larger number of determinations has been made. Brown and Morris (*loc. cit.*) co-ordinate the specific gravities of the sugar solutions and the corresponding solution densities. In this way they express their results in the form of a curve. The authors point out that, although the actual law may be a curve, for practical purposes, the results may be represented graphically by a straight line.

In the following tables containing the mean results: Column A gives the weight of dry substance taken. Column B gives the total weight of solution. Column C gives the specific gravity of the solution at 15.5° C., referred to water at the same temperature. Column D gives the grams of sugar per 100 reputed c.c. (fluid grams at 15.5° C.). Column E gives the divisor for the calculation of grams of sugar per 100 reputed c.c. from the specific gravity.

starch; Short review of our knowledge of —. A. R. Ling. Seventh Int. Congr. Appl. Chem., London, 1909.

The author draws attention to the meagre information on starch in the general treatises on organic chemistry, which he ascribes to the fact that it is a colloid, a class of substances to which laws as yet undiscovered apply in addition to those known in conjunction with crystalloids. He points out that the view that the starch molecule may be represented by such a formula $(C_6H_{10}O_5)_n$ is erroneous, since starch like all other polysaccharides must be derived from the monoses by a process of dehydration and condensation. Polysaccharides may accordingly be represented by the general formula $(H_2O)_n - n - 1(H_2O)$, which in a mathematical sense identical with that proposed by H. Kiliani (Chem. Zeit., 1908, 32, 366), namely $(C_6H_{10}O_5)_n - H_2O$. Since the value of n in the higher polysaccharides is a high one, it is not surprising that the results of the elementary analyses of starch agree closely with the limiting formula $H_{10}O_5$ of the text-books. The work of Fernbach on amylocoagulase and that of Maquenne and Roux is regarded as indicative that starch is a mixture of polysaccharides of different complexity, but of similar type. The author regards the molecule like that of all colloids mobile and as a physiological rather than a chemical entity. He is unable to accept the existence of the so-called amylopectin of Maquenne and Roux as established, resting as it does on purely circumstantial evidence. Dealing with starch hydrolysis, the author regards the result No. 8 equation of Brown and Heron as untenable, even in the form in which it is presented by Brown and Heron, who make provision for the now known reducing power of the so-called stable dextrin, thus:—

published work with J. L. Baker having shown that the amount of maltose obtainable from a starch conversion tried down to this limit is much less than indicated by the equation, and that malto-dextrins soluble in 80 per cent. alcohol are present. The author points out also that although when starch paste is treated with malt extract at 55°, the constants of the products ultimately agree with those of maltose, other bodies, notably niewsky's dextrinose, can be isolated. He cannot reject the conclusion of E. Fournard (Compt. rend., 1909, 3, 502; this J., 1909, 433) that, because starch in solution when treated with increasing quantities of alkali is in rotatory power until the constant of maltose is reached, starch is therefore to be regarded merely as condensed maltose. It is well known that under some conditions dextrose is a product of the hydrolysis of starch diastase which enzyme does not hydrolyse maltose.

starch; Hydrochloric acid extraction method for the polarimetric determination of —. L. T. Thorne and E. H. Jeffers. Seventh Inter. Congr. Appl. Chem., London, 1909.

This method, originally proposed by Dubrunfaut, modified by Efront, Ost, Lintner and others, the main sources of error are the risk of hydrolysis if the acid be too strong or the temperature too high, and the risk of perfect extraction or of partial reprecipitation if the

acid be too dilute at any period of the operation. The authors have obtained the best results by the following modified process. Five grammes of material, previously reduced to the finest possible state of division, are placed in a mortar and triturated with successive small additions of water till the mixture just ceases to cling to the pestle in lumps. This generally requires less than 20 c.c. of water. Hydrochloric acid of sp. gr. 1.15 is then added, with continued trituration, in portions of about 5 c.c. at a time, until the mass first swells up into a jelly and finally breaks down into a somewhat viscous liquid. This requires about twice as much acid as the water first used, unless the original material contained much moisture, when the quantity of acid required is somewhat greater. The mixture is allowed to stand for about 10 minutes and is then transferred to a 200 c.c. calibrated flask, into which has been previously measured 10 c.c. of a 4 per cent. phosphotungstic acid solution and 20 c.c. of hydrochloric acid of sp. gr. 1.15. The mortar is rinsed with dilute hydrochloric acid (sp. gr. 1.1) and the whole made up to 200 c.c. with dilute (1:1) acid. After mixing, the contents of the flask are transferred to a wide-necked, stoppered bottle and thoroughly shaken (or placed in a centrifugal machine) till a well-defined flocculent precipitate is obtained and the supernatant liquid is fairly clear. After filtration, the polarimetric reading of the solution is taken. With a 200 mm. tube, the Schmidt-Haensch scale and white light, the percentage of starch is given by the formula

$$P = \frac{R \times 40}{11.6}$$

With this method the concentration of acid never materially exceeds or falls below a sp. gr. of 1.1, danger of hydrolysis or precipitation is obviated, and very accurate and reliable results are obtained. The process may be very conveniently and safely used in the determination of starch in cereals, including malt, and may be employed as a check on malt extract determinations.

Starches; New microchemical distinction between rye and wheat —. W. Lenz. Seventh Int. Congr. Appl. Chem., London, 1909.

If a trace of rye starch, in a hanging drop of a solution of 1 part of sodium salicylate in 11 parts of water, is examined under 200-fold magnification, at the ordinary temperature, it will be found that after the lapse of an hour (more distinctly after 24 hours), most of the large granules have swollen; only a small part resists the action of the salicylate, and still shows the polarisation cross between crossed nicols. In the case of wheat starch, only a few of the large granules become swollen; after 1–24 hours, the outline of the unswollen wheat starch granules is sharply defined, and the granules, unlike those of rye starch, do not become flattened (starch of any kind which has been altered by storage in a moist condition, swells on treatment with the salicylate solution). Barley- and millet-starches only swell to a small extent. Only a few of the granules of oats, maize-, rice-, potato-, bean-, pea-lentil-, and arrowroot starches become swollen.—L. E.

Alcohol: Manufacturing tax on — in France. Board of Tr. J., June 24, 1909. [T.R.]

A PRESIDENTIAL Decree (sanctioned by the Law of the 24th December, 1908) fixes the rate of the manufacturing tax on alcohol and products with an alcoholic base, from the 1st January, 1909, at 2 fr. 52 c. per hectolitre of pure alcohol.

Germinating barleys: Explanation of the beneficial effect of lime water on —. P. Ehrenberg. Z. ges. Brauw., 1909, 32, 253—257, 268—271, 277—280.

THE author reviews the literature of the subject and then describes a number of experiments on barley and linseed treated in various ways. The results show that the real foundation of the beneficial influence of lime on barley lies in the prevention of mould-development. This prevention depends on the alkaline action of the lime water, it being found that mould growth is facilitated by increasing the acidity of the steep-liquor. Solvent or coagulating action of the lime water on injurious mucous walls of bacterial or mycological origin is without influence in this connection.—T. H. P.

Maltase of buckwheat. J. Puerte. Compt. rend., 1909, 148, 1526—1527.

MALTASE has hitherto only been recognised in a few seeds such as maize and *Soja hispida*. The author now finds it is present in relatively large quantities in buckwheat. The critical points for solutions of this maltase are: maximum 72°, minimum 3°, optimum 55° C. The activity of the naturally alkaline solution is stimulated by the addition of acid in quantities of less than 3 c.c. of N/10 acid per 100 c.c., and restricted by addition of more than this amount. Amino-acids and amides exert a similar influence. The soluble maltase disappears rapidly from the grain during germination but an insoluble maltase appears in its place, as the dried residue left after exhaustion with water rapidly hydrolyses a maltose solution with which it may be mingled. (See also this J., 1909, 254, 434.)—R. L. S.

Enzymes of pressed yeast juice: Action of various antiseptics on —. F. Ducháček. Biochem. Zeits., 1909, 18, 211—227.

TRACES (0.1 per cent.) of phenol too small to prevent any action on fragments of living protoplasm hardly affect the fermentative power of yeast juice. 0.5 per cent. of phenol destroys all living protoplasm and reduces the fermentative power by about 40 per cent. 1.2 per cent. of phenol renders the zymase inactive. Chloroform (0.8 per cent.) hardly affects the fermentative power; a reduction to 0.5 per cent. causes a distinct increase in fermentative activity, but larger quantities destroy the enzyme although the chloroform is not completely dissolved. Probably the chloroform is decomposed and the products affect the enzyme. Chloral hydrate (0.7 per cent.) acts as an efficient antiseptic and increases the fermentative power by 27 per cent., the effect being particularly marked in pressed yeast juice preparations of relatively small activity. It is no doubt due to the effect of the antiseptic in destroying the proteoclastic enzymes and so indirectly assisting the fermentative enzymes. An addition of 3.5—4 per cent. of chloral hydrate destroys the zymase, of which the stronger preparations are least affected by large doses. 0.1 per cent. of benzoic or salicylic acid, which is enough to produce aseptic conditions, does not affect the zymase. Quantities of 0.2 to 0.25 per cent. destroy 20 to 35 per cent. of the fermentative activity. All the antiseptics at first act unfavourably and destroy zymase; subsequently the proteoclasts are affected and the fermentative power increases. The experiments yield fresh support to the view that the fermentation by pressed yeast juice is enzymic and not vital in character.—E. F. A.

Saccharin in beer: Detection of —. G. Jörgensen. Ann. des falsific., Feb., 1909; Woch. Brau., 1909, 26 148.

500 c.c. of the beer are concentrated to a syrup on the water-bath, and then extracted with 96 per cent alcohol by trituration in a mortar. The alcoholic solution is poured off, and the residue dissolved in a small quantity of water and again triturated with alcohol, these operations being repeated once or twice. The clear alcoholic solution after standing overnight is distilled and subsequently evaporated, after addition of water, to expel the alcohol and the residual aqueous solution is treated with a few drops of dilute sulphuric acid, filtered if necessary, and shaken with ether. The ethereal extract, containing nearly the whole of the saccharin, is evaporated to a small volume, and after addition of some water and dilute sulphuric acid, is treated with a saturated solution of permanganate until it remains pink. A saturated solution of oxalic acid is added to reduce the separated manganese dioxide, excess being avoided, and the colourless solution is then filtered, shaken several times with a mixture of ether and petroleum ether, and the extract distilled. If saccharin be present the residue consists of white crystals having a very sweet taste. The presence of saccharin may be confirmed by converting it into salicylic acid in the usual manner, any salicylic acid originally present having been destroyed by the permanganate.—A. S.

Saccharin in beer: Detection of —. F. Pawlowsk. Z. ges. Brauw., 1909, 32, 281.

THE author finds that Jörgensen's method (see preceding abstract) is capable of showing the presence of 0.001 per cent. of saccharin in beer. The formation of an emulsion when the residue is extracted with ether and the consequent difficulty of separating the two liquids are both avoided by adding a very small quantity of ethyl alcohol to the liquid.—T. H. P.

Brewers' pitch: Testing —. J. Brand. Z. ges. Brauw., 1909, 32, 265—267.

THE author has devised a method for the estimation of brewers' pitch of the volatile constituents, which have their origin in the colophony used in the manufacture of the pitch and are mainly responsible for the pitchy taste imparted to beer. The method consists in passing a slow current of air for 1½ hours over the pitch (100 grms.) heated at 200° C., collecting the distillation products and weighing them and measuring their acidity. It is found that the purity of a pitch is related directly to the acidity of its distillation products, the degree of acidity diminishing as the purification proceeds. The heating is carried out in a retort, connected with a U-tube and a washing flask to retain the condensable products. A simpler procedure, which quickly gives rough results, consists in heating a small quantity (about 3 grms.) of the pitch in a test-tube in a sand-bath at 200° C. The upper portion of the tube is placed a piece of litmus paper moistened with N/10 alkali containing 20 per cent. by volume of glycerin, the latter being added to prevent the paper from drying. Impure pitch will often cause a reddening of the litmus paper before the temperature reaches 200° C., whilst with purified samples some time elapses before the colour of the paper changes.—T. H. P.

Inversion of sucrose by invertase. Hudson. See XVI.

Catalase of malt and mineral catalysers. H. van Lee. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1906, 489, 550; 1907, 161).

THE properties shown by the "catalase" of malt are considerably modified by the hydrogen and hydroxyl ion. The catalytic power, measured by the volume of oxygen liberated in the first minute, increases up to a maximum as the hydroxyl ions in the hydrogen peroxide are increased. The maximum is reached when the mixture of grist and hydrogen peroxide has a reaction nearly neutral to phenolphthalein. By reducing the alkalinity of the mixture with methyl orange by the addition of small quantities of acid the catalytic power decreases. Dry malt meal may be

ated at 125° C. for two hours without entirely destroying catalytic activity; this only disappears after heating to 200° C. If c and c' be the volumes of oxygen liberated in one minute by p and p' grms. respectively of two lots of the same malt, one of which has been heated at high temperature (105°—125° C.), and if j be the volume of oxygen liberated by a mixture of $p+p'$ grms. of the two malt grists, then j is always less than c . The difference between j and c is always greater the higher the temperature at which one of the meals has been heated. Thus the influence of the heated meal is equivalent to the introduction of hydrogen ions. The quantity of oxygen evolved in one minute increases with the quantity of malt, but is not proportional to it. This affords a ready means for establishing the identity of two samples of malt or barley. If the volume of oxygen liberated by mixing with p grms. of one sample of malt or barley grist, p' grms. of another sample, is increased, the two samples are probably identical; if the volume is diminished as the result of the mixture, the two samples cannot be identical even if their separate catalytic powers be the same. The progressive increase of the catalytic power of a barley during germination and its decrease during kilning do not necessarily imply an increase or decrease in the quantity of catalase; there may simply be a modification of the conditions due to the action of the hydrogen and hydroxyl ions. The soluble salts of the magnetic metals have no action alone on hydrogen peroxide. They act only when they are more or less converted into hydroxides by the addition of an alkali. The active agent appears to be a couple formed by the metal and the hydroxyl ion, blood charcoal, purified animal charcoal, and reduced platinum show the same relations towards the alkalinity or acidity of the medium as malt catalase. The only difference which appears to exist between the mineral catalysts and malt catalase is that that the latter is destroyed as the result of its action and disappears in whole or in part when heated to a sufficient temperature.

—J. F. B.

Enzymes of barley and malt. M. Holderer. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author has demonstrated the presence of the following enzymes in barley and malt:—Emulsin, rennet enzyme, intensase, trehalase, cellulase, and sucrase. (Cellulase decomposes cellulose into two molecules of dextrose). Barley also contains tyrosinase, and perhaps reductase and lipase; malt perhaps contains tyrosinase and lipase, but does not contain reductase.—L. E.

Bacteria of interest in the fermentation industries; New researches on —. W. Henneberg. Seventh Int. Congr. Appl. Chem., London, 1909.

IN the fermentation industries a complete knowledge of the habits and morphology of all the bacteria liable to affect the products at the various stages is of the highest importance. Of the numerous species of fission fungi adhering to the raw materials, relatively only a small number are capable of developing in the worts and mashes at the concentrations employed. These may be classified as follows:—(a). Lactic acid bacteria; (b). butyric acid bacteria; (c). slime and gas producing bacteria; (d). "coli" bacteria; (e). "hay" bacilli. The following new notes are communicated in connection with these various classes: (a). *B. Delbrücki*, the "culture lactic acid ferment," in the year 1908 about 8000 cultures were disposed of in distilleries and pressed yeast factories; 25 agar cultures were sent to lactic acid factories, "Weissbier" breweries, &c. Most of the lactic acid factories employ this ferment. Important points to observe are: Suitable temperature and nutrition, the behaviour of the ferment in molasses worts, and protection from infection. Volatile acid-lactic acid bacteria are extremely dangerous; the formation of cetic acid is frequently due to these species. Flocculating lactic acid bacteria bring about the flocculation disease of yeast and the failure of the "head" in yeast factories working on the old system. (b). Butyric acid bacteria bring about the fermentation of the yeast crop. *B. Delbrücki* is not very susceptible to this infection. In worts rich in sugar they form only a little acid but a large quantity of gas. Their effect on the culture yeast is to be feared. (c). This class

of bacteria produceropy mashes, large quantities of gas and low yields of alcohol. They have a bad effect on the culture yeast, and induce nitric acid fermentation. (d). "Coli" bacteria cause the production of gas in cereal mashes. They have a bad influence on the culture yeast and induce nitrous acid fermentation. (e). Many of the "hay" bacilli will not grow in mashes and worts because of the natural acidity of the liquid. *B. megaterioides* produces no gas but causes nitrous acid fermentation and has a bad influence on culture yeast and lactic acid ferments. *B. mesentericum* causes the "ropiness" of bread. It does not occur in pure pressed yeast, but possibly exists in the starch which is mixed with the yeast for bakers' use.—J. F. B.

Mulling, malt and lactic digestion in yeast manufacture. A. Sorel. Seventh Int. Congr. Appl. Chem., London, 1909.

DETERMINATIONS of extract, soluble nitrogen and diastatic power of malts are insufficient to allow of the yield of yeast being controlled; the quality of the raw grain and malt used and the method of working exert considerable influence, but lactic digestion has the most potent effect on the yield of yeast. The best procedure, and one which obviates the loss occasioned by the transformation of part of the sugars into lactic acid, consists in concentrating a portion of the vinasse obtained and incorporating it with the yeast when saccharification has been effected. The solution of the phosphates and insoluble nitrogenous compounds of the grain commences immediately and heating is unnecessary, the duration of mashing being greatly reduced. The development of lactic and other organisms is thus avoided almost completely, whilst the solution of the salts and the hydrolysis of the proteins into peptones and amides are enhanced. When saccharification is effected, the necessary well-sterilised vinasse should be incorporated and the whole mass maintained for 2 hours at 55—60° C. before cooling and pitching; in this way, a medium is obtained containing increased proportions of assimilable matters. Further, greater yields of alcohol and yeast are formed, the latter with augmented fermenting power.—T. H. P.

Do the raw cereal products used in brewing contribute any yeast food to beer wort? F. Wyatt and E. Schlichting. Seventh Int. Congr. Appl. Chem., London, 1909.

THE results of the experiments are embodied in three tables, and are considered to show conclusively that: (a) No appreciable amount of protein is contributed from the raw cereal product to beer or distillery worts, either by digestion or by enzymic action, or by prolonged boiling under atmospheric pressure, or under steam pressure of from 10 to 30 pounds; (b) any and all soluble protein existing in raw cereal products is coagulated by boiling with hops; and (c) the amount of nitrogenous yeast food contained in worts, made from mixed malt and unmalted cereal mashes, will always be in direct proportion to the kind and quantity of malt used.

Saccharin [in beer, &c.]; Reaction of —. J. Wanters. Seventh Int. Congr. Appl. Chem., London, 1909.

WHEN saccharin is heated with sulphuric acid and dresorcinol, it yields a product which, when treated with water and filtered, gives an intensely violet liquid. Oxidation of the residue left by the ethereal extract of beer, wine, &c., by means of potassium permanganate yields a product which is sufficiently pure, after extraction with ether, to give this reaction.—T. H. P.

Fermentation process (Guillaume, Eyrol, and Grangi system): Continuous — without dilutions. L. Millet. Seventh Int. Congr. Appl. Chem., London, 1909.

THIS process is applicable in beetroot and artichoke distilleries, but not in the case of products the fermentation of which must be carried out in desired stages. The fresh juice is introduced into continuous fermentation vats which are so contrived that the scums and deposits may be drawn off as desired. The partially fermented juice is withdrawn from these vats into another set of vats, in which the fermentation is completed. This withdrawal

of partially fermented juice is so regulated as to maintain the volume of juice in the continuous fermentation vats, in a state of maximum fermentative activity; if the density of the juice withdrawn tends to increase, the rate of withdrawal is decreased, and inversely. This process insures a uniform fermentation; the fresh juice is introduced into a mass which is always in a state of maximum fermentative activity, and the alcoholic ferments are therefore always in the best possible condition to resist invasion by objectionable organisms. With this process also, it is much easier to keep the temperature at the point most favourable to fermentation.—L. E.

Alcoholic fermentation; Assimilation of malic acid by pure yeast and formation of lactic acid in —; the independence of these two phenomena. W. Mestrezat. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1908, 763.)

When a must containing malic acid is subjected to alcoholic fermentation, part of this acid disappears, the amount varying with the species of yeast. With one and the same yeast, the amount of malic acid which disappears is greater for a medium rich in nutritive principles, such as grape must, than for an artificial medium, such as yeast water. The amount of malic acid used up in this way may be increased by repeating the fermentation after removal of the alcohol and addition of sugar. Thus, with three different yeasts, after three successive fermentations of yeast water containing 4 grms. of malic acid per litre, it was found that 3.00, 2.70, and 2.20 grms. respectively of the acid had disappeared in the three cases. These observations explain the fact that the acidity of fermented products is usually less than that of the initial must, notwithstanding the formation of succinic acid. The formation of lactic acid, which appears to take place in all alcoholic fermentations, is not a result of the disappearance of malic acid, as it is observed with cheek solutions containing no malic acid. Different yeasts yield widely varying proportions of lactic acid, and some of the organisms occurring in wine, such as *Mycoderma vini*, even consume it with avidity.—T. H. P.

Lactic acid in America. W. H. McLauchlan. Seventh Int. Congr. Appl. Chem., London, 1909.

To prepare lactic acid in the laboratory, about 400 grms. of commercial glucose, known to the trade as 70 per cent. grape sugar, are dissolved in about 1200 c.c. of hot water preferably in an agate ware pot. To the hot solution, about 170 grms. of whiting, or any well-powdered calcium carbonate, is added, and 20 grms. of malt, which has been previously boiled a few minutes in 100 c.c. of water. The whole is kept simmering gently for half an hour to sterilise the raw materials; it is then allowed to cool to 60° or 70° C., and after stirring well to bring the calcium carbonate into suspension, it is poured into a narrow-mouthed bottle, having a capacity of two or two-and-a-half litres. A little more water, used to rinse out the calcium carbonate, is poured into the bottle until the volume amounts to some 1800 c.c. The bottle is then stoppered with a wad of cotton, and placed in the air bath or incubator, which is kept at a constant temperature of 45° C.

For fermentation experiments, an air bath much larger than usual is needed. This can be easily made from a sheet-iron oven, and the temperature should not vary more than one degree. The metal disc thermo-regulators used for incubators are accurate enough for this purpose, but are not satisfactory with much variation in the gas pressure. After the bottle and its contents have cooled to the air bath temperature it is ready to be inoculated with a lactic acid ferment. The pure culture may be prepared by first sterilising in a number of test tubes, sweet milk. These tubes, after sterilising, are closed with a cotton plug and placed in the air bath. Number one tube is then inoculated with a drop of sour milk; a day later number two tube is started from number one tube, and number three from number two, and so on, until the seventh tube is supposed to contain a pure culture. For experimental purposes one may proceed

at once using either sour milk or casein to start the fermentation. Only a few grains are required, and in five or six hours after introducing the ferment, the progress of the fermentation can be noticed by the evolution of carbon dioxide when the bottle is agitated. The shaking should occur every six hours, or oftener, although the bottle may be allowed to stand overnight, and if the fermentation is proceeding properly the evolution of gas upon shaking the calcium carbonate with the supernatant sugar-lactic acid solution will be quite vigorous. Samples of the solution are pipetted out each day and tested for the per cent. of calcium in solution, which indicates the progress of the fermentation and the consequent formation of calcium lactate. At the expiration of a week or ten days the per cent. of calcium remains stationary, or increases very slowly, and a sample is tested to see if any unfermented sugar remains. If this is less than 0.4 per cent., the fermentation may be considered finished. The calcium lactate solution is treated with the calculated quantity of sulphuric acid, and after stirring well, a test tube full is filtered and tested with a drop of sulphuric acid, to be sure that acid sufficient to precipitate all the calcium, as calcium sulphate has been added. When this point has been reached the calcium sulphate is removed by filtration. The impure lactic acid in the filtrate can be freed from volatile constituents by evaporating. On concentrating, more calcium sulphate separates out, which must be again removed by filtering. The final filtrate should amount to about one litre of 25 per cent. lactic acid. The acid thus obtained is not perfectly colourless, but can be decolorised with animal charcoal.

If the calcium lactate solution be allowed to cool after the fermentation is finished, calcium lactate, which is much less soluble at ordinary temperatures, separates from the solution. The mother liquor may be squeezed out and the calcium lactate washed in small quantities of cold water. This washed calcium lactate after being dissolved and decomposed with sulphuric acid yields a colourless strong solution of lactic acid.

The details for preparing lactic acid have been given because the process for making it on a commercial scale is, in principle, identical with the method just given for preparing it in the laboratory. The various operations to be carried out are:—1st. Preparing solution for fermenting. 2nd. Fermenting. 3rd. Decomposing the calcium lactate. 4th. Filtering out the calcium sulphate. 5th. Concentrating.

The solution.—When the raw material consists of starch corn (maize), grain, or other material in which the source of the sugar is starch, this must first be inverted by the action of dilute acids or malt diastase. In either case the grain must be first ground, and if the inverter is to be accomplished with acid, the grain or starch is placed in a large wooden tank, and sufficient water to agitate the material is added, followed by about 2 per cent. of sulphuric acid. The temperature is raised to, and kept at, 95° C. for five or six hours by means of live steam. When inverting with malt, about 10 per cent. of the weight of the material to be inverted is used. The temperature in this case is 65° C. If glucose or other fermentable sugars are used as raw material inversion is unnecessary. The glucose is dissolved and pumped into the fermenting tank. To the sugar solution is now added enough finely powdered calcium carbonate to neutralise all the acid which can be formed by fermentation from the sugar, the object being to remove the free acid, as more than 1 per cent. stops the action of the lactic acid bacteria. Calcium carbonate containing free lime may be used, although it is commonly thought that no lactic fermentation would occur with an alkaline substance present. The lactic bacteria require as nutriment a certain amount of nitrogenous matter. This is present in grain, but when fermenting solutions of sugar, this nitrogen must be supplied. Peptone may be used in the laboratory, but gluten meal, casein, malt, or grain are used in manufacturing. This material is generally "digested" in a weak sulphuric acid solution before running into the fermentation tank. The amount used should be such that the nitrogen corresponds to 0.1 per cent. of the sugar. The use of inorganic salts containing nitrogen, nitrates,

ammonium salts, and phosphates has been recommended seemed unsatisfactory both for a laboratory experiment and in actual practice. When the sugar, calcium carbonate, and nutrient matter have been brought into a tank, water is added, and the solution stirred, until a specific gravity corresponds to 15 to 17 per cent. sugar. In order to sterilise, before starting the fermentation, live steam is blown in through a perforated lid in the bottom of the tank until the temperature rises to 95° C., where it is held for an hour, and then the solution is allowed to cool to 45° C., and is now ready for inoculation with the lactic acid germs. The lactic acid ferment may be prepared as directed for making small amounts of lactic acid, using, however, a large copper pan about one hundred litres capacity, kept at the fermenting temperature in a large incubator or box kept at constant temperature by a steam coil. The fermentation tank, made of cypress wood, is ten to sixteen feet in diameter and six to eight feet in height, provided with a steam pipe for heating, which can also be used as the pipe for stirring with compressed air. These pipes are of lead or copper, and there is a lead pipe connection from the floor of the tank leading into a pipe laid along the side of the fermentation tanks, through which the fermented liquor is pumped. The tank is covered, and has a manhole which can also be used to introduce the materials required for making the solution. The tank is also supplied with a thermometer and a spigot on which samples for daily tests are taken. The fermentation should begin in a few hours after "starting" with the lactic ferment, and should go rapidly the first few days, and then less rapidly as the sugar concentration decreases. Sometimes the fermentation stops before sugar is used up. In this case the liquor is again sterilised should any foreign organisms be present, and started again with more of the lactic acid culture. The worst foe to a "clean" fermentation seems to be the lactic fermentation. Should this appear, the calcium lactate is decomposed and hydrogen is liberated, which is responsible for the explosions which occur when a naked light is used in a tank containing liquor fermenting improperly. Some acetic and formic acids are occasionally produced, but in no case should these volatile acids amount to more than 5 per cent. of the lactic acid present. When the fermentation is over, the solution is heated by steam preparatory to pumping to the tank in which the sulphuric acid is added. After neutralisation, the calcium sulphate is allowed to settle, and the clear lactic acid drawn to a storage tank. One half the volume in the tank, containing the calcium sulphate, is still left. To this, a weak acid from the filter press is added. The contents of the tank are well stirred, and allowed to settle. Again the clear liquid is drawn off, and the remainder, containing the calcium sulphate and the diluted acid, is sent through a plunger pump to the filter press. The liquor from the press is added to that from the decomposing tank. When the press is full it is washed until the wash water is free from acid, the strong wash waters being stored for washing the calcium sulphate in the decomposing tank, the weak wash water being used in making up new charges. The acid, except that to be used for washing the calcium sulphate, is evaporated to 22 per cent., the strength of which most of it is sold. Occasionally some is sold at 50 per cent. This concentration is accomplished in a copper vacuum pan, supplied with a steam belt or coil and a "juice catcher" between the pan and the condenser. The pan may be heated by exhaust steam. The finished acid is light coloured when made from glucose or starch, but dark brown when made from grain or other materials containing colouring matter. The specific gravity of the 22 per cent. acid is about 1.1. The calcium lactate may be crystallised out from the liquor after fermentation, and then washed free from other liquor and dissolved in a small amount of water. The washed calcium lactate, decomposed with sulphuric acid, gives an acid light in colour, and free from soluble impurities. This operation is not followed in America because the consumer is not particular about the colour of the acid, and further, calcium lactate is a difficult salt to handle. It does not crystallise well, and is quite soluble even in cold water. The laboratory

tests, which have been referred to, may be carried out as follows:—

Free acid is determined by titrating a sample, after settling, against N/5 sodium hydroxide, using phenolphthalein as the indicator. *Calcium lactate, or combined acid*.—10 c.c. of clear liquid are diluted to 150 c.c., and heated to boiling. It is then titrated with a standard solution of sodium carbonate, 1 c.c. of which represents 0.5 per cent. of lactic acid. The indicator is phenolphthalein. *Sugar*.—This is determined as given in Lunge's *Chemisch-technischen Untersuchungs Methoden*. 10 c.c. of Fehling's solution, heated to boiling, are titrated against the sugar solution, from which the calcium is first precipitated. In the finished acid it is necessary to determine the total free acidity, the anhydride and volatile acids present, as well as the ash, and sulphuric acid. *Free acid*.—About 20 grms. are weighed out and diluted to 250 c.c. 25 c.c. of this solution are titrated direct for total acidity. *Anhydride*.—25 c.c. more are boiled with a known excess of N/5 sodium hydroxide for ten minutes, and then, after adding enough N/5 acid to more than neutralise the sodium hydroxide, the solution is titrated with N/5 sodium hydroxide, using more phenolphthalein. The difference between the first determination and the second equals the amount of anhydride present. This ordinarily amounts to 5 or 10 per cent. of the total acidity. *Volatile acids*.—They are determined by taking 25 c.c., of the same diluted solution, evaporating to one-half the volume and diluting with water to 20 c.c., repeating the operation two or three times. This is not accurate, as lactic acid is slightly volatile, but it answers the demands of the trade, and will give results which can be duplicated if the operation is carried out in the same manner. *Plant*.—In all chemical processes depending upon a fermentation, it is well understood that a scrupulous cleanliness must be observed; therefore, a lactic acid plant must be arranged so that it can be kept clean and free from all chance of contaminating the fermentation. The floors should be built of cement so that they may be flushed off with water. The fermentation tanks should be placed so that the floors beneath and the walls next to them can be easily kept clean. In addition to the inverting, fermenting, and storage tanks, ten or twelve in all, a steam plant, a 40 horse power engine, air compressor, vacuum pan, filter-press, four pumps, a lead-lined acid tank, and iron sulphuric acid storage tank are required. Such a plant could be built for 15,000 dollars, and would have an approximate capacity of 100 tons of 22 per cent. lactic acid per month. The demand for lactic acid is not great enough to warrant the establishment of a plant for its sole manufacture. In America, at least, it is made only by concerns engaged in the manufacture of other chemicals as well. Most of the lactic acid is sold to the tanneries where it is used as a so-called "plumper." The hides are heated with dilute lactic acid, which prepares them to receive the further treatment in the process of tanning. Lactic acid has thus a restricted market.

Wines of South-West France: Alterations in the sulphurous acid added to the musts of — and causes of variations in the ratio of reducing sugars to polarisation. P. C. Mestre. Seventh Int. Congr. Appl. Chem., London, 1909.

THE principal factors which influence the transformations undergone by the sulphurous acid in grape musts are: the aldehydes, the enzymes, the sugars, the air dissolved in the must, and the air absorbed during its storage in recipients of various nature. Some of these factors are themselves influenced by the degree of maturity of the grapes and by the changes brought about by the attacks of insects or parasitic plants. It is practically impossible to lay down any rule as to the maximum and minimum proportions of sulphur dioxide which determine the starting up of fermentation in musts which have been treated with sulphur dioxide. It depends so much on the biological condition of the must at the moment of removing the sulphurous acid and the quantity of that agent which was present. In any case, vinification proceeds very slowly even when pure yeast is used, not only when polarisation shows a predominance of levulose, but also in musts containing normal proportions of dextrose

and levulose. This sluggishness, which is accentuated when the removal of sulphurous acid is followed by pasteurisation, is, in 80 per cent. of the cases, accompanied by the production of quantities of glycerol far in excess of those calculated by Pasteur. This is why the wines prepared from treated musts are always fuller flavoured than those prepared from the same musts untreated. The ratio $\frac{P}{a}$ represents the ratio of the weight of reducing sugars, determined by Fehling's solution, to the polarimetric reading. This ratio is used for calculating the proportions of dextrose and levulose and for determining whether the sweet taste of a wine is due to the introduction of unfermented grape juice. The author has shown that certain pure musts occur in which this ratio has a value indicating proportions of dextrose and levulose such as occur in partially fermented juices. This anomaly is extremely common in the districts suffering from the attacks of *Cochylis* and *Endemix*, and is produced by the parasitic fungi which follow these attacks. Under their action the dextrose disappears to a greater or less extent, sometimes without the production of alcohol. Often the presence of this latter is observed very distinctly in the juice of the grapes whilst still on the vine. The most numerous cases of these abnormal musts are those in which the grapes have become more or less oxidised on the vine and are more or less rich in by-products of oxidation.—J. F. B.

Pasteurisation of wines; New method of —. C. Mariller. Seventh Int. Congr. Appl. Chem., London, 1909.

THE wine is heated to a definite temperature by the vapours from suitable liquid mixtures. These mixtures are boiled by means of either direct fire or a steam-coil, the pressure of the vapours acting on a regulator which controls the entry of steam to the coil or the access of air to the fire. The vapours, after use, are condensed, slightly cooled, and returned to the liquid bath. By this automatic process, superheating is avoided and the wine preserves its initial composition.—T. H. P.

Fermented liquids; Formation, variation, and evolution of esters in —. Kayser and Demolon. Seventh Int. Congr. Appl. Chem., London, 1909.

IN this investigation, the authors have dealt chiefly with ethyl acetate, which some yeasts produce in relatively considerable quantity, and which constitutes almost the whole of the volatile esters; the study of the fixed esters is more difficult. The authors point out that during fermentation, the formation of esters by chemical interaction of the fermentation products, is quantitatively negligible. If a series of fermentations, in which varying amounts of volatile acids are produced, is carried out in flasks placed under the same conditions, the quantity of volatile esters is approximately proportional to that of free volatile acids. The ratio, free volatile acids : volatile esters, varies with the experimental conditions; it decreases in deep media, and may approximate to 2, no special precaution being taken to avoid losses. Direct addition of acetic acid does not increase the proportion of esters, and hence, the theory of a synthesising enzyme acting in the external medium, should be rejected. The fact that distillation of the yeast itself, in presence of water, always yields a certain quantity of esters, shows that the ester-formation occurs in the interior of the yeast cell. With free exposure to air, the esters rapidly decrease on completion of fermentation, even if mercuric chloride is added to prevent their destruction by the yeast. Experiments, in which ethyl acetate was added to various media, showed that about 60 per cent. disappeared in 9 days at 12° C. It is the escaping carbon dioxide, however, which is largely responsible for the loss of esters formed during fermentation.—L. E.

Brandy; The nature of the esters of — and the factors which influence their proportions. C. Ordonneau. Seventh Int. Congr. Appl. Chem., London, 1909.

THE distillate from 10 hectolitres of lees of wine from Borderies de Cognac has been examined for the characterisation of the volatile acids and esters. There were

found: formic, acetic, butyric, crotonic, caproic, and cœnanthic acids, as well as their ethylic esters and free lactic acid derived from the fermentation of the malic acid. Ethyl acetate represents about 92 per cent. of the esters of the wine and cœnanthic ester about 7 per cent which explains the richness in esters of the "head" products of the distillation. From the rectification of 20 hectolitres of brandy, the author has isolated 30 grms. of ethyl formate and 3400 grms. of ethyl acetate. The chief factors which influence the quantities of the volatile acids in brandy, and consequently those of their esters are: the quantity of volatile acids existing in the wine, the duration of the distillation, and the total acidity of the wine. The proportions of volatile acids in wines are variable, and diseased wines are the richest. The brandies distilled in the old-fashioned stills with a slow fire are always richer in esters than those distilled in a rapid still, because prolonged ebullition of the wine favours the esterification of the volatile acids, as is illustrated by the distillation of a mixture of vinasse and neutral spirit which on slow distillation yielded 40 grms. of esters per hectolitre of absolute alcohol. Whilst admitting that the presence of esters in a mixed spirit in no way implies that wine brandy is present, the author concludes that since the best brandies are obtained by slow distillation in an old-fashioned still, they ought to be rich in esters, but that in practice care should be taken to ascertain that these esters are not derived from damaged wines, which may be done by tasting.—J. F. B.

Alcohol, its impurities, and its denaturation; Action on the common metals of —. R. P. Duchemin. Seventh Int. Congr. Appl. Chem., London, 1909.

THE following table gives the dry residue in grms. per litre of alcohol after being left in contact with the various metals for three months:—

	Iron.	Tin.	Zinc.	Copper.	Brass.
Ethyl alcohol, 95°	0.0	1.3	2.2	1.1	1.4
" " " + 50 per cent. water	10.8	2.5	8.3	1.0	2.1
" " " + 10 per cent. aldehyde	1.5	1.4	3.0	0.8	1.0
" " " + 10 per cent. ethyl acetate	3.4	1.0	4.7	0.8	0.8
" " " + 10 per cent. amyl acetate	1.0	1.2	8.4	2.2	3.0
Methyl alcohol, 95°	1.5	0.3	1.8	0.9	1.1
" " " + 50 per cent. water	13.8	0.9	13.6	0.4	0.5
" " " + 10 per cent. acetone	1.3	1.2	1.6	2.0	2.0
" " " + 10 per cent. methyl acetate	0.9	1.5	3.8	0.6	2.0

It will be seen that it is the impurities present in denatured alcohols which render them inconvenient for use with metallic plant.—T. H. P.

Vinasse charcoal; Losses of salts in the production of —. E. Bauer. Seventh Int. Congr. Appl. Chem., London, 1909.

A CAREFUL comparison of the quantity of salts fed into the furnace in the form of concentrated vinasse with the recovered in the charcoal shows a loss ranging from 5 to 10 per cent. This loss on burning consists principally of potassium sulphate, which fact is apparently not in concordance with the fact that the dissociation temperature of potassium sulphate is considerably higher than that of the carbonate and chloride. A portion of this sulphate is deposited in the flues near the furnace in the form of a fusible crystalline mass as hard as stone, whilst further quantities are deposited as dust nearer the chimney. It is assumed that in the body of the furnace the sulphate is reduced to sulphide, which volatilises on dissociation and is subsequently condensed and re-oxidised in the flues. This re-oxidation is not always complete, and many of the samples drawn from the flues contain sulphide. The quantity of salt recovered from the flues varies, according to the temperature and the length of the flues, from 8 to 12 per cent. of the total loss. The greater portion equivalent to from 5 to 10 per cent. of the calculated

eld of crude ash, goes up the chimney. This loss is greater in the Ganur furnace than in the Porion type, in which latter a portion of the volatilised salt is absorbed by the sprays of liquid vinasse.—J. F. B.

Creatinine determination [in meat extracts, &c.]; Factors which influence the —. F. C. Cook. J. Amer. Chem. Soc., 1909, 31, 673—693.

THE author has made a large number of experiments on the colorimetric determination of creatinine under varied conditions (see this J., 1907, 709; 1908, 87). It was found that with commercial samples of creatine and creatinine, slightly higher results were obtained when 10 c.c. of picric acid were used than when 15 c.c. were used; with meat extracts the results were the same whether 15 or 30 c.c. of picric acid were employed. It is advisable to always add 25 or 30 c.c. of picric acid, since an excess does not influence the results. The amount of alkali which gave the most satisfactory results was 10 c.c.; an excess caused the results to come out lower. Serious errors may be caused by the dilution of the creatinine solution before the addition of the reagents. The error due to dilution is a fairly constant one. If the result obtained with 10 c.c. of the creatinine solution be taken as correct, then for each 10 c.c. of dilution, 0.00019 grm. of creatinine less is found. Thus if the solution is diluted to 100 c.c., $0.00019 \times 9 = 0.00171$ grm. should be added to the result. The result obtained is also lower the longer the solution is allowed to stand after the addition of the reagents; it is recommended that the period of standing be 5 minutes. Somewhat low results are obtained if coagulable proteins (egg albumin), proteoses, or peptones are present, and although ordinary meat extracts do not contain sufficient protein to seriously affect the results, yet in exceptional cases, it is necessary to remove the protein before applying the test. For the conversion of creatine into creatinine, a modification of Benedict and Myers autoclave method (Amer. J. Physiol., 1907, 13, 397) proved most satisfactory. 50 c.c. of the meat extract solution are well mixed with 50 c.c. of $N_{1/1}$ hydrochloric acid, heated in

the autoclave for 15 minutes under 15 lb. pressure, then the volume adjusted to 100 c.c., and an aliquot portion taken for the creatinine determination.—A. S.

Jelly-making; Chemistry and physics of —. N. E. Goldthwaite. J. Ind. and Eng. Chem., 1909, 1, 333—340.

THE author defines a jelly of good texture as one that is not tough; that will quiver but not flow when shaken; and that can be easily cut by means of a spatula into pieces, which will preserve their shape. Experiments with crab-apple, sweet apple, grape, pear, peach, and plum juices showed that the essential constituents for the formation of jellies of good texture are pectin and free acid, whilst sucrose is a desirable accessory constituent. For fruit juices of sp. gr. about 1.04, the most desirable proportion of free acid is about 0.5 per cent. (expressed as sulphuric acid). After addition of an acid (organic or mineral) to a fruit juice containing little free acid, good jellies can be made, but the flavour is impaired and in some cases completely spoiled; tartaric acid gives somewhat better results than citric acid. The amount of sugar required appears to depend mainly upon the proportion of pectin in the juice; too much is generally used. It is probably best to add the sugar so that it is boiled with the juice for a period not exceeding one-half the total time of boiling. With crab-apple juice, jellies of excellent texture and with remarkable keeping qualities can be obtained by using glycerin in place of sugar. Tests with different fruit juices showed that hot juice ready to gelatinise on cooling, has a b.p. of about 103° C. and sp. gr. (observed with a hydrometer), 1.28. Pectin was isolated from different fruit juices by boiling them, then cooling and filtering, and adding the filtrate drop by drop, with constant stirring, to an equal volume of alcohol. After standing overnight, the pectin was collected on a filter of fine cotton cloth, and the liquid worked out of the gelatinous mass by means of a spatula. After repeated re-dissolving and re-precipitating, the pectin was obtained as a nearly colourless, transparent solid. By preparing a 1 per cent. solution of the pectin from sweet apple, crab apple, and peach juices in a 0.5 per cent. solution of tartaric acid, heating to boiling, adding 0.75 volume of sugar, and again boiling until a test-portion gelatinised on cooling, jellies of excellent texture and taste, but nearly colourless, were prepared.—A. S.

Rice; "Facing" and other methods of preparing — for sale. J. M. Hamill. Report to the Local Government Board, New Series, No. 4, 1909.

THE normal creamy white colour of rice is changed to one of dead whiteness by the addition during the milling process of ultramarine or aniline colouring matters. Prussian blue or indigo are also used but less commonly. If the grain is not to be glazed, the opacity is subsequently modified by arachis oil or carefully purified petroleum, about 3 gallons of oil sufficing for 200 cwt. of finished rice.—J. W. G.

Flour; Bleaching and conditioning of —. W. Jago. Seventh Int. Congr. Appl. Chem., London, 1909.

RECENT milling developments have had as their object the improvement of the colour of flour. The colour of flour is more or less due to the presence of the following colouring matters: Bran, crease, and other outside, dirt, colouring matter of the endosperm. Bran contains a reddish-brown colouring matter. If very fine particles of bran are allowed to remain in the flour, they darken the colour, and this is intensified when the colour is dissolved out in the act of making dough. Crease dirt, when allowed to get into the flour, gives it a sad, bluish-grey tint. This outside dirt is removed by scouring or washing the wheat, and also by first splitting the grains longitudinally and removing the crease flour before proceeding further with the reduction of the grain. Colouring matter of endosperm.—This is in a different category, being a part of the flour itself. In properties, the colouring matter is somewhat unstable in character, and diminishes very noticeably on keeping the flour some

two or three months. The intensity of such colour varies considerably; some flours, such as that of Walla Walla wheat, are very yellow, while others are comparatively white. Some years ago the writer made experiments on these flours with ozone. The colour was almost completely destroyed, but the flour acquired an unpleasant taint.

Since then other bleaching agents have been proposed, the most important being nitrogen peroxide, and, secondarily, chlorine. The whole of such bodies, and also ozone, are either direct or indirect oxidising agents. But the bleaching is not necessarily an oxidising action, because sulphur dioxide, a reducing agent, also bleaches flour. Nitrogen peroxide is by far the most important of these bleaching agents, and for that purpose is produced either by chemical processes or a flaming electric discharge through air. There has been much discussion as to whether bleaching by nitrogen peroxide is due to oxidation or to nitration. Advocates of the former view point out that nitrogen peroxide undoubtedly acts as an oxidising agent in certain well-known reactions, and that it is fair to assume that it also does so on flour. The fact that ozone bleaches the flour is quoted in support of this argument; but the reply is made that electrically produced ozone contains nitrogen peroxide, which is really the effective bleaching agent. The argument in favour of the nitration theory is that the oil of the flour, with which the colouring matter is closely associated, absorbs the nitrogen peroxide, being chlorinised. In support of this view the oil is shown to be altered in character, and nitrogen compounds of the nitrite type can be detected in the treated flour. One argument is surely not destructive of the other; oxidation of colouring matter may co-exist with absorption of nitrogen peroxide, *i.e.*, there may be both oxidation and nitration. When flour is kept, it "ages" or "conditions." A conditioned flour works rather better during fermentation, usually makes a better coloured and rather larger loaf, and absorbs rather more water. It is claimed for bleaching that it "conditions" the flour. Conditioning consists probably in alterations in the physical characters of the gluten. Gluten may be too tenacious in quality, and while ageing, it may be slightly broken down by traces of acid, so that it can expand more freely. If as a result of such changes the flour as a whole has improved, fermentation goes on more regularly. As bleaching by nitrogen peroxide causes the development of traces of acid, this treatment may cause quickly the same changes as occur more slowly in flour during ageing, but all must depend on whether or not the flour is in such a condition as to be improved by such changes. But bleaching does not change a low-grade flour into a higher one; the colour may be lightened, but the other characters of the flour are not transformed. Bleached flour should therefore be declared as such.

Wheatn flour; Gas-making capacity as a factor in the estimation of strength in — A. E. Humphries and A. G. Simpson. Seventh Int. Congr. Appl. Chem., London, 1909. (See this J., 1907, 985).

THE final conclusion is that the total gas evolved in panary fermentation is of no importance as a measure of strength; the gas evolved in the latest stages of fermentation is of greater significance and it is a factor under the control of the miller and the baker. The progress of these later stages of fermentation is dependent on the action of the various diastatic enzymes present in all wheaten flours.

Milk; Comparative study of the new methods of detecting watering of — G. Cornalba. Seventh Int. Congr. Appl. Chem., London, 1909.

EVEN the milk from large herds exhibits moderately large natural variations in the amounts of residue, fat and casein, so that quite a large addition of water may be necessary in order to bring these amounts down to the minimum values. With the milk from a single animal these variations are still more marked. The author finds that a sure means of detecting dilution of milk with water is furnished by the sum of the soluble components of milk. Taken separately, these soluble components give no reliable data, as their amounts vary somewhat widely; but their sum varies only between such narrow limits as to render possible detection of a dilution as small as 5 or even 4 per

cent. The mean value of this constant for mixed milk from a number of animals is about 6.25, the limiting value being 5.95 and 6.46. For the milk of single cows, the limiting values are 5.80 and 6.60, and with the majority of the cows the value oscillates round the number 6. Taking the mean value 6.15, addition of 5 per cent. of water to the milk would lower the value to 5.81. Determination of the density of the serum, which should not be less than 1.030, is capable of revealing dilution of milk to the extent of 10 per cent.

Evaporated milk and milk products; Analysis of — E. Gudeman. Seventh Int. Congr. Appl. Chem., London, 1909.

A NEW method for the determination of fat in concentrated milk and in milk products is given as follows:—2.5 grms. of the milk product are weighed into a beaker and dissolved, or made into an emulsion with about 100 c.c. of water. In this solution fat, and proteins, and substance insoluble in water (cereals, starch, gums, fibre, etc.) are precipitated with copper sulphate (Fehling solution). The precipitate is filtered off and washed on the filter, and the dried between filter paper, or at a very low temperature, and directly extracted in a continuous extractor with petroleum ether, and the extracted fat dried on the water-bath and weighed. The advantage claimed for the method beside accuracy and rapidity, is the fact that the extracted fat is not modified by excessive drying before or after extraction. The extracted precipitate can be used for the determination of protein, insoluble in water, the Kjeldal digestion being complete within one hour. With product containing a large amount of fats, such as milk chocolate, milk powders and others, a preliminary extraction with dry ether, petroleum ether, or other suitable solvent is recommended. The method was found to have extensive application in the analysis of products containing sugar, starch, cereals and other substances that interfere with direct extraction of the products.

Dried potatoes; Preparation and uses of — E. Parow. Seventh Int. Congr. Appl. Chem., London, 1909.

POTATOES are dried so as to contain not more than 15 per cent. of moisture, either by means of superheated steam or by hot gases. In the first place the washed potatoes are boiled soft, using steam under a pressure of 0.5 atm. The boiled potatoes are then passed between rolls to which steam under a pressure of 2.5 atm. is supplied, the steam given off from the potatoes being removed by an exhaust. The paper-like mass obtained is scraped off the rolls by sharp knives, and torn into flocks. In the second system the washed potatoes are cut up into pieces or discs, which are then passed through fixed or rotating drums through which hot gases from burning coke or coal, plentifully mixed with air, are drawn by an exhaust arrangement. The temperature in the drums is 120°–250° C., that of the exhaust gases 100°. The total cost of drying 100 kilos of potatoes by the first process is from 8½d. to 1s. 2½d. and by the second process from 6½d. to 9½d. Dried potatoes can be used for all purposes for which fresh potatoes are used, and keep indefinitely. In Germany 200 installations, with about 300 machines, have been constructed so far, capable of dealing with about 600 million kilos. of potatoes per annum.—A. G. L.

Cocoa; Presence of oxalic acid in — C. Girard. Seventh Int. Congr. Appl. Chem., London, 1909.

EXAMINATION of authentic samples of cocoa showed that they contain as much oxalic acid as is found in sorrel, spinach and rhubarb, and that the quantity is not diminished by drying. Analyses of the chief brands of cocoa and of their ash are given.—A. G. L.

Oxalic acid in cocoa and chocolate. J. M. Albahary. Seventh Int. Congr. Appl. Chem., London, 1909.

EXISTING methods having failed to give accurate results in the determination of oxalic acid in cocoa or chocolate the author devised the following process, which is based on the fact that in an alkaline solution magnesium salt precipitate phosphates and purino bases, whilst oxalic

did remains in solution as magnesium-alkali oxalate; calcium oxalate is also soluble in an alkaline solution. About 50 grms. of the sample, which has been dried over sulphuric acid till of constant weight, are heated for one hour on the water-bath with 50 c.c. of a 10 per cent. solution of sodium carbonate, fresh water being added to replace that evaporated. The mixture is then treated with 50 c.c. of a solution containing 10 per cent. of magnesium chloride and 20 per cent. of ammonium chloride, a quantity of animal charcoal being also added to retain mucilaginous substances. After concentrating by liquid by heating for another hour, with occasional agitation, the mixture is filtered whilst hot, with the aid of the pump, and the insoluble matter is washed with boiling water. The filtrate is concentrated, made strongly ammoniacal, and after standing for 12 hours, is filtered. The filtrate is treated with a slight excess of calcium chloride, then made faintly acid with acetic acid, and after standing for 12 hours in a warm place, the precipitated calcium oxalate is filtered off, and the oxalic acid determined in the usual way. This gives the total oxalic acid: the preliminary heating with sodium carbonate being omitted, the oxalic acid present as soluble alkali salts is determined, and the difference between the two results gives the quantity present as calcium oxalate. With this method it was found that a specimen of "alkalised" cocoa powder contained per kilo., 3.647 grms. of oxalic acid in the form of soluble salts and 0.188 gm. as calcium oxalate; in a sample of "non-alkalised" cocoa powder, the corresponding figures were 0.159 gm. and 3.763 grms. In two specimens of chocolate, 0.7238 and 0.385 gm. respectively of oxalic acid per kilo. were found.—A. S.

Gelatin; Copper as an impurity in —. W. B. Hart. Seventh Int. Congr. Appl. Chem., London, 1909.

METALLIC impurities, when found in cooked and preserved foods, generally originate from the cooking vessel, the packing vessel, the sealing material such as solder, rubber ring, etc., or from the intentional addition of copper salt for "greening" purposes. The author has traced a further and hitherto unrecorded source of metallic impurity. Pressed beef, alleged to have caused symptoms of poisoning, when microscopically and bacteriologically examined, was found to be quite sound, but a small quantity of copper was detected, the origin of which was eventually traced to the gelatin used as a garnish, the results being as follows:—

	Mgrms. of copper per kilo.
Pressed beef 1	34
Pressed beef 2	0
Gelly preparation	69
Gelatin A	25
Gelatin B	104

The examination of a number of samples of gelatin, sold for household use gave results varying from 0 to 56.3 mgrms. of copper per kilo., and the figure varied directly with the price. Possible sources of copper contamination during the manufacture of gelatin, and the widely divergent opinions of various authorities as to the permissible limit for copper in foods are referred to.

Foodstuffs; Mineral constituents of —. H. Ingles. Seventh Int. Congr. Appl. Chem., London, 1909.

THE necessity for a sufficient supply of "mineral matter" or "ash constituents" in the food of animals has long been acknowledged, but the importance of its composition has not been sufficiently recognised. Sodium, chlorine, fluorine, iron and calcium are apparently of more importance to animals than to plants and are not stored in any considerable quantities in the seeds of plants, which are usually rich in potassium and phosphorus compounds. In seeds and in cereal seeds particularly the proportion of phosphorus pentoxide far exceeds that of lime, while in the stems and leaves of most plants—of *Leguminosae* especially—the lime largely predominates. Further consideration shows that the food supplied to animals, is not sufficiently varied in character, must often be deficient in certain mineral elements which are essential to the proper formation of digestive and other secretions. The various secretions required for normal digestion

and growth in an animal are characterised by containing certain chemical elements, some of which occur but rarely in plants.

Thus, iodine, contained in the thyroid secretion, and fluorine, an essential constituent of bone and teeth, are not abundant in plants, while the ratio of sodium, chlorine, iron and calcium to the potassium and phosphoric acid required by animals is far higher than exists in most plants. As an example of what the writer believes to be a widespread fallacy, the view that wheat bran is particularly valuable as a "bone-forming" food may be cited. This substance is particularly rich in ash and contains a large amount of phosphorus pentoxide (about 3.0 per cent. of its weight) but only about 0.2 per cent. of lime, and, according to the writer's view, should be very unsuited for bone development and nutrition, as indeed is the case, as proved by the existence of a curious bone disease, known as "bran rachitis," among horses fed largely on bran.

Food colours, certified; Difficulties in the way of their manufacture. E. G. Kohnstamm. Seventh Int. Congr. Appl. Chem., London, 1909.

THE coal-tar colours permitted under the Food and Drugs Act of the United States are seven in number, which must be in a high state of purity. The author states that none of the colours on the markets of the world, at the time of testing, would meet these requirements. Of these seven colours, 189 samples from every possible source, and representing all the leading manufacturers, are here reported on, and the results of their examination reasonably establish the necessity of food colour certification. Of these 189 samples the worst were offered for food colouring purposes and seemed to be so offered because unfit for any other purpose. *Naphthol Yellow S*.—Sixty-four samples examined, ranging in shade from clear bright yellow to a dirty brownish or green colour. All contained Martius' Yellow, some more than 1 per cent. thereof; some contained as high as 2 per cent. and even 3 per cent. of unconverted initial material or decomposition products. Forty-one contained excessive arsenic and 29 excessive heavy metals. *Orange 1*.—Twenty-eight samples examined; all contained decomposition products, varying from a slight amount to over 50 per cent.; free α -naphthol was found in most samples, in 12 it was as high as 2 per cent.; insoluble matters were as high as 1 per cent.; lead to the extent of 0.5 per cent. was found in one sample; shading by added colours and excessive amounts of arsenic, lead and iron were frequent. *Amaranth*.—Thirty-eight samples examined; none were pure, and all contained arsenic in excessive amounts, and in one case as high as 0.1 per cent.; all contained added colour, principally an acid-violet. Iron as high as 0.1 per cent.; insoluble matter as high as 1½ per cent.; was most heavily loaded with salt of all seven colours. *Ponceau 3R*.—Thirty-six examples examined; the purest of all colours tested; not toned; heavily loaded with salt; much insoluble matter was present; decomposition products were absent; iron 0.01 per cent.; 12 contained excessive amount of arsenic, and 14 contained excessive amount of heavy metals. *Erythrosine*.—Twelve samples examined; 10 were not erythrosine at all; of the other two, one was low in iodine and one contained arsenic. *Light Green S.F. Yellowish*.—Thirteen samples examined; only one free from arsenic, nine contained lead or copper, one contained manganese; none were loaded. *Indigo-disulphonic acid*.—Eight samples examined; none were pure; the iron content was as high as 1.5 per cent.; all were loaded with salt or Glauber's salt. One contained excessive amount of arsenic and two excessive amounts of heavy metals. The difficulties consist in keeping the undesirable materials out of the dyes, or in separating them from the crude dyes, or both.

Flour: Aping, conditioning and bleaching — F. H. Loring, London. Eng. Pats. 12,780 and 12,781, June 15, 1908.

(1). The process consists in the exposure of flour to the vapours of chlorides or oxychlorides of sulphur, mixed with a large volume of air or other inert gas, either with or without subsequent aeration. To these vapours may be added formic acid or the usual bleaching agents.
(2). The flour is treated with a large volume of air or other inert gas containing small quantities of formic acid or formic aldehyde or other compound of the same type. A smaller quantity of the flour may be treated with excess of the vapours and then be mixed with a large quantity of untreated flour.—J. H. J.

Impregnating liquids with carbonic acid; Apparatus for — H. Kummeler and Co., Aarau, Switzerland. Eng. Pat. 24,813, Nov. 18, 1908. Under Int. Conv., Sept. 22, 1908.

AN improved form of draw-off pipe and gas-inlet passage combined, for attachment to an atomiser impregnating chamber is described. The draw-off pipe is connected with a new form of bottle-filling apparatus by means of an extension tube terminating in a filling nozzle and passing through a hollow arm with which it communicates by a snifting passage. The bottle to be filled is supported in a holder and can be pressed by a spring against the filling nozzle. The draw-off pipe has a cock with a wide bore for admitting the impregnated liquid into the bottle and with a snifting passage for allowing the compressed air in the filled bottle to escape.—J. H. J.

Putrescibility test for sewage and sewage effluents; Experiments on the — D. D. Jackson and W. A. Horton. J. Ind. and Eng. Chem., 1909, 1, 328—333.

THE authors have tried to ascertain the best conditions for determining the putrescibility of sewage and sewage effluents by the incubation test. It is recommended that the sample be diluted with varying quantities of distilled water saturated with air at 20° C., and incubated for 4 days at 37° C. in presence of an indicator, the decolorisation of which is taken as an indication of putrescence. The most sensitive indicator is commercial "methylene green" (the double zinc salt), 1 c.c. of a solution containing 0.5 gm. per litre being used; larger quantities have a slight antiseptic action. In order to avoid leakage during incubation, the test-bottle is fitted with a perforated rubber stopper carrying a glass tube drawn out at the lower end and closed above by a rubber bulb. After filling the bottle, tube, and bulb, the latter is squeezed flat and will then allow for expansion during the incubation.—A. S.

Water. Influence of chlorides on the determination of nitrates in — [by Grandval and Lajoux's method]. G. Perrier and L. Farcy. Ann. Chim. analyt., 1909, 14, 213—215.

IS the original method, nitrates are determined by evaporating 10 c.c. of the water to dryness on the water-bath, moistening the cold residue with 1 c.c. of a mixture of 12 grms. of phenol and 144 grms. of sulphuric acid of sp. gr. 1.767, and after a few minutes' contact, adding 10 c.c. of water and 10 c.c. of dilute solution of ammonia. The yellow colour is then matched with that produced under similar conditions, by a solution of 80 mgrms. of potassium nitrate in a litre of water. The authors find that the action of hydrochloric acid on this colour reaction is by no means negligible, even when derived from the amount of chlorides usually present in well waters. With waters containing larger quantities of chlorides, such as exist in the wells of maritime districts, the determination of nitrates becomes quite erroneous by this method, since the hydrochloric acid liberated lessens the depth of the yellow colour to a considerable extent. If, however,

an amount of sodium chloride, equivalent to the amount of chlorine found to be present to the water, be added to the standard potassium nitrate solution taken for the colour control, the results obtained will be strictly comparable.—J. O. B.

Trade-effluents; Disposal and purification of — G. J. Fowler and E. Arden. Seventh Int. Congr. Appl. Chem., London, 1909.

The polluting effect of trade-effluents may be due to the presence of:—

- (a) An excessive quantity of suspended solids;
- (b) Substances capable of fermentation or putrefaction and consequent production of nuisance;
- (c) Colouring matters, such as vegetable or artificial dyestuffs;
- (d) Substances poisonous to aquatic vegetation, or fish-life;
- (e) Oily matters, fat and soap.

The detailed description of these various classes of effluent and their respective methods of treatment is briefly indicated in the following paragraphs, it being understood that one effluent may fall under more than one head.

(a) Tannery effluents contain large quantities of lime in suspension, effluents from plants for the recovery of ammonia from liquors produced in the distillation of coal in gas-retorts or coke ovens contain large quantities of calcium salts in suspension, and effluents from coal washing plants contain much fine coal in suspension; potter effluents contain clay, effluents from aniline stills may contain large quantities of magnetic oxide of iron, effluent from dye and bleach works may contain much flocculent matter from waste "filling" or mordanting substance and fibrous material from the cloth itself, paper mill effluents may also contain fibre and "filling." Most of these can be clarified by simple subsidence in suitably constructed settling tanks. In certain cases—e.g., paper mill effluents, mechanical filters or fine screens may be employed.

(b) Among important fermentative or putrefactive effluents are those from breweries or distilleries, from tanneries and hide-dressing works, from beet-root sugar manufactories, starch works, wool-scouring works, bone manure and glue manufactories.

All of these can be purified by suitably arranged biological tanks and filters either before or after admixture with sewage. It should be noted that liquids capable of undergoing acid fermentation—e.g., starch effluents or brewery effluents are not well suited to anaerobic treatment. (c) Colouring matters from dye works may be of vegetable origin such as indigo or logwood or belong to the numberless varieties of so-called "aniline" or artificial dyestuffs. The former and certain of the latter—e.g., alizarin derivatives—which are fixed mordants can be precipitated by means of iron or aluminium salts. A large proportion of artificial colouring matters are not capable of removal in this way. They are generally destroyed in biological filters when mixed with sewage, but, apart from their colour, do not constitute a dangerous element in effluents. (d) A great variety of injurious substances may be discharged under this head, e.g.,—

Alkali sulphides from alkali waste heaps, from the vulcanising of india-rubber, from dyeing process employing sulphur dyestuffs, and in certain cases the effluents from ammonia recovery stills. It is highly important that these should be treated with excess of lime or with a mixture of lime and ferrous sulphate (copperas), and the precipitated sulphide settled off in tanks, before the effluent is discharged either into a sewer or a watercourse, or there is almost a certainty of serious nuisance or even fatal accidents, arising from the evolution of sulphuretted hydrogen due to the contact of such an effluent with free acid.

Acids and alkalis, unless present in very minute portions, should be neutralised before discharge into stream or sewer.

Chlorine, either in the free state or as hypochlorite, bleach works effluents, unless present in very large quantities, is not likely to be very troublesome when

charged into a sewer, but it is important from the point of view of fish life and aquatic vegetation, that only minimum quantities should be allowed to pass direct into a stream.

Numerous tarry products, such as benzol and naphthalene washings containing sulphonic acids of benzene and naphthalene, various phenolic derivatives, etc., are very injurious to the microscopic life of streams, and may in some cases quite upset the natural balance of aquatic life. When sufficiently diluted and mixed with sewage they are amenable in general to biological treatment. The same applies to the very troublesome effluents from ammonia stills treating the liquor from the distillation of coal in retorts or coke ovens. In addition to phenolic derivatives these effluents contain thiocyanates, thiophosphates, and sometimes sulphides. The effluents from paper and cellulose works obtained after boiling away cellulose material with alkali sulphites, is very difficult to treat and is generally evaporated.

(e) Free particles of grease and fat, e.g., from tripe-pressing works, etc., can usually be intercepted by specially devised grease traps. Soaps, e.g., such as are produced in wool scouring works, are first decomposed by acid, when the fatty acids rise to the surface and can be separated and purified. In the case of ordinary laundries it is often simpler to precipitate the soaps with lime.

Law as to trade-effluents.—The difficulties of interpretation of the law are to be found in the liability of local authorities to take trade-effluents into sewers, when these were insufficient in size, or when, the sewers being adequate, the purification works were over-burdened. A further difficulty has arisen in regard to responsibility for pollution of a stream, when a manufacturer discharges into a sewer belonging to a local authority.

All of such cases have been decided on appeal, in a sense favourable to the local authority. It is generally the wish of the local authority to encourage manufacturers as far as possible, and several towns have special bye-laws of their own, obtained generally by mutual agreement with manufacturers, confirmed in some cases by special Acts of Parliament. Thus the towns of Halifax and Bradford have power to impose a charge upon manufacturers according to the volume and quality of the effluents sent into the sewers. Manchester has special powers regulating the composition of the effluent discharged into the sewers, but does not make any charge or treatment. These powers are based on similar ones possessed by the London County Council.

The Royal Commission on Sewage Disposal recommended in their third Report of 1903, that in general, local authorities should receive trade-effluents into sewers, but that either preliminary treatment should be adopted by the manufacturer, or that he should pay a special charge to go to the cost of treatment of his effluent. Points of difference likely to arise between manufacturers and local authorities the Royal Commission recommends should be referred to the Central Authority, which it is of opinion should be appointed.

Sewage; Physical and biolytic factors in the purification of — J. H. Johnston. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1907, 428.)

Two series of experiments on the practical scale are described to illustrate the retention of colloids and matter in solution in a sewage passing through a filter and the biolytic action on the matter so retained. The first experiment consisted in passing tank effluent, sterilised as far as possible with steam, on to a trickling filter filled with sterilised material. In this way the number of bacteria passing on to the filter was reduced to 200 per c.c., and that in the effluent from the filter was 250 per c.c. It was found that retention of organic matter in colloidal and ordinary solution took place from the very first, the effluent being nearly clear. Absorption of ammonia took place at first and soon decreased, but was resumed when the absorbing surface was renewed by nitrification of the already absorbed ammonia; this latter took place after the twelfth day. The purification was as effective as if the liquid had contained the usual number of organisms.

The second experiment consisted in applying tap water to a mature trickling filter which had been standing unused for a fortnight. The first effluents were low in ammonia and very high in nitrate, showing the great amount of biolytic action which had been taking place on the organic and other matters in the filter while resting. After the products of this action had all been washed out, there was evidence in the effluent of slow formation and nitrification of ammonia and continuous removal of the organic matter which had been absorbed during preceding ordinary operations.

Green seaweeds; Nuisances caused by — in tidal waters; and a special method of sewage treatment to minimise their growth. E. A. Letts. Seventh Int. Congr. Appl. Chem., London, 1909.

THE author's experiments have shown that the growth of green seaweeds of the *Ulva* and *Enteromorpha* species in tidal waters is mainly due to the presence of ammonium salts and, to a less extent, of nitrates, derived from sewage. The following method of sewage treatment has therefore been recommended to the Belfast Corporation:—(1). Removal of solid matter by means of screens, catch pits, and continuous flow sedimentation. (2). Treatment of a portion of the sedimented sewage by percolating filters followed by a short period of sedimentation. (3). A process of denitrification consisting in submitting a mixture of the highly nitrated effluent from the percolating filter with the septic tank effluent, to treatment on a contact bed, so as to effect a destruction of nitrates in the one and purification in the other. Experiments on a large scale have given good results, and it is estimated that the method will effect a reduction of over 80 per cent. in the factors that promote the growth of these seaweeds in Belfast Lough.—C. A. M.

Water for potable purposes by means of chlorine or hypochlorites; Purification of — J. C. Thresh. Seventh Int. Congr. Appl. Chem., London, 1909.

SINCE the process of slow sand filtration was inaugurated early in the last century very little advance has been made in the methods of purifying waters for potable purposes. The great advantage of storing polluted river waters for a period, before filtration, has recently become more fully recognised, but the great expense entailed in the construction of reservoirs, and slow sand filters, leads one to think that processes may yet be devised which will be more economical than storage and slow sand filtration.

The process which appears most likely to be successful is the use of chlorine or hypochlorites. These chemicals have been used in emergencies, but on account of the disagreeable effect upon the palate of the residual chlorine, their use has been abandoned as speedily as possible. The author recently (Dec., 1908) drew attention to the fact, that when waters were fairly free from suspended matter and from organic matter in solution, exceedingly minute quantities of chlorine sufficed for practical sterilisation, far smaller quantities than had hitherto been employed, and that by the subsequent use of sodium bisulphite the residual chlorine could easily be removed and the water rendered as palatable as before. The author has shown that with many waters, one part of chlorine per million practically sterilised them, and that the cost for chemicals did not exceed 5s. per million gallons treated.

His recent experiments have been more especially devoted to ascertaining whether the residual chlorine could not be removed by some process of filtration which would at the same time remove any trace of suspended matter, and wrought-iron turnings appear to give the best result. After passing through the iron the water contains a small portion of the metal, probably as bicarbonate, in solution, and some oxide in suspension. By mere filtration through sand nearly all the iron is removed, but it is preferred to use a filtering material called "polarite," since this removes the iron better, and will also remove any trace of chlorine which has not been taken up by the iron.

Ozone: Sterilisation of water at Nice by —. Beunat.
Seventh Int. Congr. Appl. Chem., London, 1909.

For the last 15 months the water at Nice has been successfully sterilised by means of the Otto ozone apparatus. The plant installed is capable of dealing with 1000 cb. m. per hour, but so far only 228—837 cb. m. per hour have been treated. The ozonised air is generated in 40 elements consisting of adjacent plates of glass covered with tin, which are cooled by a coil containing water; the air is drawn in through a central hole in one of the plates. A continuous electric current of 110 volts transformed into an alternating current of 20,000 volts, with a frequency of 500, is used. The ozonised air obtained contains 0.9—3.3 mgms. of ozone per litre; at least 0.33 gm. of ozone per cb. m. of water is necessary to effect sterilisation. The water is mixed with the ozonised air in 8 emulsifiers, each consisting of a double cone with their apices together; the water issues from the upper into the lower, into which the treated air is also passed. The results obtained are very satisfactory; besides effecting sterilisation, the ozonised air also diminishes the organic matter in solution by 13—34 per cent.—A. G. L.

Nitrites in sanitary water analysis: Fuchsine-S as a permanent standard for the determination of —. J. H. Kastle and E. Elvyne. Seventh Int. Congr. Appl. Chem., London, 1909.

The pink colour produced by a nitrite and Griess' sulphanilic acid- α -naphthylamine reagent can be exactly matched by a solution of Acid Magenta (Fuchsine-S; Acid Fuchsin according to Weigert), which has been acidified with hydrochloric acid. A solution of the dyestuff is prepared by dissolving 0.2 gm. in 50 c.c. of 2N-hydrochloric acid and making up to 2000 c.c. with distilled water. Of this solution 100 c.c. are mixed with 50 c.c. of 2N-hydrochloric acid and diluted to 2000 c.c. with distilled water. From the latter solution (No. 2), standard solutions are prepared containing varying quantities which are mixed with 5.0 c.c. of 2N-hydrochloric acid and made up to 200 c.c. with distilled water. The number of c.c. of solution (No. 2) and the equivalent of "nitrite" nitrogen in parts per million are as follows:—

c.c. of Solution No. 2	1.5	2.4	3.9	5.5	7.1	8.7	12.6	16.5
Equivalent of "nitrite" nitrogen	0.0005	0.001	0.002	0.003	0.004	0.005	0.0075	0.01

The standard solutions are made up fresh about once a month and kept in a cool place away from direct sunlight; the stock solution No. 2 is renewed about once in six months.—J. C. C.

(C).—DISINFECTANTS.

Disinfectants: Chemical control of —. M. W. Blyth. Seventh Int. Congr. Appl. Chem., London, 1909. (See also this J., 1905, 1183).

THE author shows that the Rideal-Walker test may give entirely different results when carried out by different observers; moreover, the action of disinfectants on organisms contained in faeces may be quite different from their action on naked organisms. Chemical examination of the disinfectant must therefore always be coupled with the bacteriological tests. Analysis is rendered difficult when emulsifying agents are present. The author recommends acetone as a de-emulsifying agent. For disinfectants containing soaps the procedure

is as follows: To 200 c.c. of disinfectant 200 c.c. of pure acetone and 200 c.c. of petroleum ether (boiling below 70° C.) are added; the mixture is extracted with 200 c.c. of water, and then with 200 c.c. at a time of a mixture of equal parts of acetone and water, until the aqueous extracts measure 800—900 c.c. The washings are then extracted with 100 c.c. of petroleum ether, which is added to the main petroleum ether solution. The aqueous extract is next made up to 1000 c.c., of which portions are taken for the determinations of emulsifying agent, i.e., free and combined alkali, resin, fatty acid, etc. A portion may be steam-distilled to see whether tar acids or hydrocarbons are still present; this should not be necessary, with the practically neutral disinfectants at present on the market. The petroleum ether solution is distilled from a large flask until the petroleum ether and water are volatilised. The residual oil in the flask is measured (allowing for that clinging to the flask) and represents total oil and free resin. The oil is then returned to the flask, distilled and again measured. The distillate is mixed with half its volume of petroleum ether, and extracted three times with sodium hydroxide solution (sp. gr. 1.2), the washings being extracted once with half their volume of petroleum ether. The two petroleum ether solutions are mixed, evaporated, and the residual hydrocarbons measured. The alkaline solution is acidified with sulphuric acid (1:3), extracted with petroleum ether, the latter well washed with distilled water and transferred to a distilling flask; the solvent and water are distilled off and the phenols remaining behind measured and fractionated as usual. Water in the disinfectant is taken by difference, but should be checked by distilling the sample and measuring the water. The result so obtained is always about 1 per cent. too low.

For disinfectants containing albumin, 200 c.c. of the sample are boiled under a reflux condenser with 200 c.c. of acetone until a homogeneous solution is obtained; 200 c.c. of petroleum ether are then added, and the analysis carried out as above.—A. G. L.

PATENT.

Antiseptics: Manufacture of new —. O. Inrray. London. From Farb- u. vorm. Meister, Lucius, und Brüning, Höchst a. M., Germany. Eng. Pat. 15,931, July 27, 1908.

MONO-HALOGEN derivatives of *m*-cresol of the type, CH_3 ; OH ; X :1:3:6, are heated with a neutral soap or a soap containing excess of fatty acid, or a sulphonated soap, producing products which are soluble in water and have antiseptic properties.—J. H. J.

XIX.—PAPER, PASTEBOARD, &c.

Metals: Action of paper on —. P. Klemm. Wochenbl. f. Papierfabr., 1909, 40, 1675—1681.

THE action of paper on metals under commercial conditions falls under two distinct heads: (1), corrosion and oxidation, such as occurs in the case of steel goods under the action of chemicals in the wrapping papers; (2), blackening, with formation of sulphides, such as may occur in the case of silver and copper articles, or in the case of decorative printing with metallic designs. The rusting of steel goods may occur not only with paper containing free acids and "chlorine," but also under the action of readily dissociable salts, particularly the aluminium sulphate used for sizing and the ferric or cupric salts sometimes employed in dyeing. The occurrence of free acid in papers is comparatively rare; it may exist in the form of free sulphuric acid, sometimes also as free hydrochloric or sulphurous acid. The presence of an injurious excess of aluminium sulphate is, however, very common, and may be regarded as the rule in the case of hard-sized papers. Its action may not be at first apparent, but under the influence of changes in the temperature and moisture of the atmosphere, rusting eventually takes place. Great caution must, however, be exercised in arriving at a conclusion in this case, since rusting may readily be induced, even when a perfectly indifferen-

aper, e.g., pure filter paper, is employed. When, for instance, a test is being made in an atmosphere containing moisture, great care must be taken to avoid changes in the temperature. If such occur, the metal, being the best conductor, becomes colder than the paper, and moisture condenses in drops upon its surface; these drops absorb carbon dioxide from the air and accumulate at the points of contact between the metal and paper, thus causing corrosion in exactly the same manner as if the paper were at fault. These conditions, of course, obtain very frequently in practice, and it may be said that no paper can really prevent rusting, unless it be gas-tight and the packet hermetically sealed. Having regard to the above circumstance, and always controlling the result by a blank test with pure filter paper, papers may be tested for their indifference to steel articles by a direct test. This is best performed under a bell jar, lined with moist paper, so as to preserve a humidity of about 95 per cent. of saturation. The jar should be protected from light, from changes of temperature, and from one-sided influences of all kinds, especially from draughts. The steel articles, consisting of a flat piece of watch spring and a piece of steel wire bent in the form of a U, should be carefully cleaned with emery paper and then handled lightly with the forceps. They are pinned twice through the paper, and the sides of the strip are then folded over them: several of such packets, together with the blank, may be clamped together. They are placed under the bell jar, in which is also placed an open dish containing caustic soda lye to absorb carbon dioxide. Good papers could remain for a week under these conditions without inducing rust. The blackening of metals under the influence of paper is more frequent now than formerly, owing to the fact that the majority of papers are prepared from some form of wood pulp which has been digested with sulphur compounds. Practically all unbleached wood pulps of the sulphite and sulphate classes contain residues of sulphur compounds which will blacken metals. Even bleached pulps are frequently contaminated. Unbleached wood pulps, straw and wood pulps prepared by caustic soda and mechanical pulps are generally free, but bleached pulps may contain residues from the "antiblocking." The active compounds include sulphites, sulphides, and free sulphur. Direct tests may be made with metallic iron on the same principle as that described above for steel. Sulphites are best detected by means of test papers impregnated with potassium iodate and starch, moistened with dilute hydrochloric acid. Sulphides and free sulphur are detected by making a decoction of the paper with 1 per cent. sodium hydroxide, acidifying the decoction by suspending a strip of lead paper in the atmosphere above the liquid. Free sulphur may be extracted by chloroform and recognised by its crystalline form on evaporation of the solvent.—J. F. B.

Canadian pulp and paper. Ch. of Comm. J., July, 1909. [T.R.]

STATISTICS issued by the Canadian Customs show that, during the year ended March 31st, 1909, the quantity of pulp exported was: To the United States, wood pulp, chemically prepared, 769,514 cwt. and mechanically ground, 3,033,885 cwt.; to Great Britain, chemically prepared, 13,660 cwt., and mechanically ground, 973,598 cwt. The export of paper during the same period was: To the United States, wall paper, rolls, 19,974, valued at \$440; felt paper rolls, 109,863, valued at \$101,835; wrapping paper, 594,695 lb., valued at \$24,264; printing paper, valued at \$791,533; paper of other kinds, valued at \$34,673. To Great Britain, wall paper, 512 rolls, valued at \$159; felt paper, 5,060 rolls, valued at \$21,896; printing paper to a value of \$922,278, and other paper a value of \$354,887. During the same period 901,861 cwt. of pulp wood were exported to the United States. The Department of Trade and Commerce has issued a statement showing a considerable decline in the importing of printing paper from the United States. For the nine months ended December 31st, 1908, the value was \$145,000; for the corresponding nine months of 1907, \$231,000; for the corresponding nine months of 1906, \$274,000. The imports of printing paper from Great Britain range from \$135,000

to \$165,000 for each nine months, and only a trifling amount was imported from any other country. The sales of wood for wood pulp to the United States have increased. In the last nine months of 1908 the value was a little over \$3,500,000, compared with a shade above \$2,000,000 for the corresponding term of 1906. No other country was a purchaser from Canada. In wood pulp the sales in the last nine months of 1908 were \$2,000,000, the same as in 1908, and \$750,000 less than in 1907.

Vegetable fibres; Chemistry of — C. G. Schwalbe. Seventh Int. Congr. Appl. Chem., London, 1909.

IN a short summary of recent studies on the effect of chemical reagents on cellulose, it appears necessary to repeat or extend former researches, such as, for instance, those of Tauss on the action of water and alkali under pressure, oxidation by alkalis, and the action of neutral salts. It is further very important to study the occurrence of the cellulose hydrates, for these correspond in properties to many varieties of cellulose. The greater or less capability of hydrolysis can be no longer considered as especially characteristic of the hemicelluloses, since it has been shown that mercerised celluloses, for instance, are very much more quickly hydrolysed than hydrocellulose or cellulose. The occurrence of cellulose hydrates in many natural celluloses has a strong influence on the results obtained by the usual methods of estimating cellulose. It has not been possible up to the present to distinguish with certainty between hydrocelluloses and oxycellulose. In the acetylation of cellulose, hydrocellulose appears to be formed as an intermediate product; when neutral salts are used in place of acids in the acetylation process, the decomposition of the salts by the cellulose is not improbable. The very necessary work from the standpoint of colloidal chemistry on cellulose problems has been hindered up to the present by lack of rational methods of investigation. (See also this J., 1909, 216).—H. P. P.

Action of oxalic acid on cellulose. Knecht. See V.

PATENTS.

Porous materials [cellulose]; Purification of — W. R. Whitney, Alplaus, N.Y., Assignor to General Electric Co., New York. U.S. Pats. 923,227 and 923,745, June 1, 1909.

THE porous material is washed with a solvent which is isotonic with respect to the impurity it is desired to remove and only contains a small quantity of it, while at the same time an electric current may be passed through the solvent, which may be a solution of an organic substance. The process is more particularly applied to the removal of zinc chloride from cellulose, by suspending the cellulose in a liquid which will dissolve the impurity and passing an electric current through the solution.—J. H. J.

Circulation of liquid especially in cellulose boilers. Ger. Pat. 209,443. See I.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Isoquinoline bases; Synthesis of — A. Pietet and E. W. Kay. Ber., 1909, 42, 1973—1979.

DERIVATIVES of isoquinoline can be prepared by the following reactions. Benzoylphenylethylamine dissolved in toluene or xylene is mixed with phosphorus pentoxide, and boiled in a reflux apparatus. Condensation takes place with the formation of a base, 1-phenyldihydroisoquinoline, $C_{15}H_{13}N$, which boils at $188^{\circ}C$ at 6 mm., and at $320^{\circ}C$ at 718 mm., and melts at 73° — $74^{\circ}C$ when crystallised from light petroleum. The hydrochloride melts at 222 — $223^{\circ}C$. If this base is oxidised in a warm acid solution with the requisite quantity of permanganate, 1-phenylisoquinoline, $C_{15}H_{11}N$, is produced. When crystallised from aqueous alcohol, it forms small needles, melting at 93° — $94^{\circ}C$. 1-Methyldihydroisoquinoline, $C_{16}H_{15}N$, was formed from acetylphenylethylamine in the

same way. It is a colourless oil, boiling at 236° C. at 735 mm. The hydrochloride melts at 160° C. Phenacetyl-phenylethylamine, $C_6H_5 \cdot CH_2 \cdot CH_2 \cdot NH \cdot CO \cdot CH_2 \cdot C_6H_5$, was made from phenylethylamine and phenacetyl chloride, and melts at 95° C. When treated with phosphorus pentoxide, 1-benzylidihydroisoquinoline, $C_{16}H_{15}N$, is produced. This substance is a basic oil, with a pleasant odour, and boils at 196° – 197° C. at 12 mm. The picrate melts at 174 – 175° C. When oxidised with permanganate, 1-benzylisoquinoline is produced, which crystallises from light petroleum and chloroform in colourless prisms, melting at 56° C. The picrate melts at 182° C.—F. SODX.

Essential oils; Constituents of —. Enol-isovaleraldehyde acetate. Enol-citronellal acetate and its conversion into an isopulegone derivative. F. W. Semmler. Ber., 1909, 42, 2014–2017.

ISOVALERALDEHYDE, was heated with acetic anhydride and sodium acetate to 200° C. under pressure. On making alkaline with sodium carbonate, extracting with ether and fractionating, enol-isovaleraldehyde acetate, $(CH_3)_2 \cdot CH \cdot CH \cdot CH_2 \cdot O \cdot CO \cdot CH_3$, was obtained. This boils at 127° – 133° C. at 760 mm., has the sp. gr. 0.8818 at 20° C., and $n_D^{20} = 1.41655$. Enol-citronellal acetate, $C_{12}H_{20}O_2$, produced in a similar way, boils at 110° – 115° C. at 10 mm., has the sp. gr. 0.902 at 20° C., $n_D^{20} = 1.45762$, and $[\alpha]_D^{20} = -1^{\circ}$. When this substance is boiled for 20 hours with acetic anhydride, and the product hydrolysed, isopulegol is obtained.—F. SODX.

Phenolphthalein in pharmaceutical preparations; Determination of —. K. Kollo. Pharm. Praxis, 1908, 7, 341–344. Chem. Zentr., 1909, 1, 1908.

THE author compared the following methods:—(1). The finely-divided dried sample was extracted with acetone, the solution evaporated, and the residue weighed. (2). The sample prepared as in (1), was extracted with 8 per cent. sodium hydroxide solution, the phenolphthalein precipitated from the solution by means of acetic acid, separated by filtration, dissolved in acetone, and then determined as in (1). (3). The sample (containing 0.4–0.6 gm. of phenolphthalein) was completely extracted with 10–15 c.c. of 8 per cent. sodium hydroxide solution; a solution containing 2 grms. of iodine and 3 grms. of potassium iodide in 20 c.c. of water was added gradually to the alkaline liquid, and the mixture acidified with concentrated hydrochloric acid. The tetraiodophenolphthalein was filtered off, washed with 90 per cent. alcohol and ether, which had both been previously saturated with the tetra-iodo-compound, dried at 100° C., and weighed. (4). The residue from the acetone extract, obtained as in (1), was boiled for half hour under a reflux condenser with about 2 grms. of acetic anhydride and sodium acetate, the reaction product washed with dilute sodium carbonate solution, saponified with alcoholic caustic soda, and the amount of alkali consumed determined; 1 c.c. of N/1 alkali = 0.318 gm. of phenolphthalein. It was found that methods (1) and (2) give results about 5 per cent. too low, but methods (3) and (4) yielded trustworthy figures.—A. S.

Lactic and glycollic acids; Very delicate reactions for [the detection of] —. G. Denigès. Bull. Soc. Chim., 1909, 5, 647–649.

LACTIC acid, even in traces, may be detected by decomposing it with sulphuric acid and causing the aldehyde produced to condense with guaiacol or codeine to give coloured products. 0.2 c.c. of the lactic acid solution (containing not more than 2 per cent. of this acid) is mixed with 2 c.c. of sulphuric acid (sp. gr. 1.84) and heated for 2 minutes on a boiling water bath; after cooling, one or two drops of a 5 per cent. solution of guaiacol or codeine in alcohol are added, and the mixture is shaken; with guaiacol a red tint can be detected with as little as 0.01 mgm. of lactic acid, and with codeine an orange or yellow colour is produced. Under the same conditions, but at a higher temperature, glycollic acid gives formaldehyde, and, for its detection, codeine, guaiacol, or *p*-cresol may be employed. 2–10 mgms. of the substance, 0.2 c.c. of water, and 2 c.c. of sulphuric acid (sp. gr. 1.84) are heated together, until small bubbles of gas are developed

rather rapidly, and, after cooling, a single drop of codeine solution is added and the mixture shaken; a yellow colour is produced, rapidly changing to deep violet. If the other reagents be employed, 1 or 2 drops of the alcoholic solution are added to the mixture before heating, together with 1 c.c. of glacial acetic acid; on heating, green colour is produced with *p*-cresol and violet with guaiacol.—F. SODX.

Methylglyoxal as a colour reagent [for phenols, alkaloids, etc.]. G. Denigès. Bull. Soc. Chim., 1909, 5, 649–651.

METHYLGLYOXAL gives characteristic colours with many cyclic compounds, particularly phenols and certain alkaloids of the morphine group. As a reagent it may be prepared as follows:—20 c.c. of water, containing 5 per cent. by weight of glycerin, are shaken with 100 c.c. of water and 0.6 c.c. of bromine, until the bromine is dissolved; the solution is then kept for 20 minutes on a boiling water bath and subsequently boiled for 5–6 minutes, so as to expel all free bromine and reduce the volume to about 100 c.c.; after cooling, 20 c.c. of pure sulphuric acid is added, and the liquid distilled, 50 c.c. of distillate being collected and constituting the reagent. The mode of using depends somewhat on the nature of the substance in question. In testing for certain phenols and alkaloids, a few mgms. or drops of the substance are added to 0.4 c.c. of the reagent and 2 c.c. of sulphuric acid (sp. gr. 1.84), and the mixture is shaken. Pyrogallol gives a deep brown colour; resorcinol, orange; pyrocatechol, red; α -naphthol, violet; β -naphthol, yellow, then green; apomorphine, violet-red, becoming deep violet on adding 2–4 c.c. of glacial acetic acid after 2 minutes' contact; oxymorphone, yellow-green on adding acetic acid; morphine, yellowish-brown; codeine, yellow, then greenish or bluish-green. In the last two cases boiling with 1 c.c. of pure acetic acid, after 1–2 minutes' contact, gives a violet colour with morphine and blue with codeine. Traces of the alkaloids in alkaloidal residues may be detected with a few drops of the mixture. In some cases (indole, scatole, and pyrrole, for example) a little of the substance is dissolved in 2 c.c. of glacial acetic acid, 1 c.c. of sulphuric acid and 1 c.c. of the reagent are added, and the mixture shaken. Indole gives a red colour; scatole, orange; and pyrrole, brown. In other cases 0.1 c.c. of a 4 per cent. solution of potassium bromide, 0.4 c.c. of the reagent, and 2 c.c. of sulphuric acid (sp. gr. 1.84) are shaken together and the mixture then again shaken with a little of the substance to be tested. Phenol gives thus a red colour, changing to orange; salicylic acid and salicylates, a violet colour; gallic acid, green; an guaiacol, blue, then violet. With some compounds only 0.2 c.c. of the reagent should be used in this last method. Homologues of benzene, under these conditions, give a red colour; naphthalene, a green colour on warming; santolin, violet on slight warming, then blue, and finally a rich green; thiophene, red, then violet and blue or green, a reaction which is very delicate and may serve for the detection of thiophene in benzene.—F. SODX.

Tartaric acid, citric acid, and cream of tartar; Impurities [lead and arsenic] in —. G. S. Buchanan. Extract from the Annual Report of the Medical Officer of the Local Government Board, 1907–8, 132.

THE amounts of lead and arsenic were determined in a large number of representative samples of tartaric acid, citric acids and cream of tartar. The results showed that much of the tartaric acid arriving in British markets has not been prepared with the care which its use as a food ingredient demanded. Limits of $\frac{1}{10}$ th of a grain of lead per lb., and $\frac{1}{100}$ th of a grain of arsenic, as arsenious oxide were therefore recommended. The former is based on a trade standard which has been in use for some time for cream of tartar, and the latter on the Final Report of the Royal Commission on Arsenic Poisoning (1903).—J. W. G.

Henbane and stramonium cultivated in Japan; Constituents of —. M. Watanabe. Seventh Int. Congress App. Chem., London, 1909.

THE dried leaves of cultivated *Hyoscyamus niger* were extracted with alcohol in three different ways, but i

case could more than a trace of the mydriatic alkaloids obtained. When, however, leaves and fruits were analysed in the same way, the alkaloids (0.021 per cent. calculated as hyoscyamine) consisting of scopolamine and a minute quantity of hyoscyamine, were isolated. In scopolamine appears to occur mainly in the fruits of the plant.

Some years ago, Shimoyama and Koshima isolated hyoscyamine, together with a small quantity of atropine, from the seeds of the plants found in the Chiba district, which are considered to be *Datura alba*. But such a result does not agree with results attained by other investigators. According to the statements by E. Schmidt, Kircher, J. Feldhaus and others, the chief alkaloid of *Datura alba* must be scopolamine. The author now repeats Shimoyama and Koshima's experiments, and obtained the same result, getting hyoscyamine (0.1 per cent.) as the main alkaloid. It is, therefore, probable that the plant is not *Datura alba*, but is, in reality, *Atropa stramonium*, the chief alkaloid of which is known to be hyoscyamine. This view was further confirmed by morphological examination.

Herba Scopolia japonica; Constituents of —. M. Watanabe. Seventh Int. Congr. Appl. Chem., London, 1909.

Dried leaves of *Herba Scopolia japonica* contain about 8 per cent. of total alkaloid, consisting of hyoscyamine, 5 per cent.; scopolamine, 5 per cent.; and a minute quantity of atropine.—F. SHOX.

Eupatorium rebaudianum (Paraguay sweet plant); Constituents of — and its pharmaceutical uses. K. Dieterich. Seventh Int. Congr. Appl. Chem., London, 1909.

The whole plant of *Eupatorium rebaudianum* was treated with water, the liquid evaporated and taken up in methyl alcohol. A dark, resinous, crude, sweet principle was obtained, which melted at 83° C. This contains two sweet principles, *eupatorin* and *rebaudin*, a bitter resin, a fatty oil, and a bitter principle. *Eupatorin* is soluble in absolute alcohol, and sinters at about 115° C. The methyl alcohol solution gives a yellow precipitate with the sodium salt with sodium hydroxide. When hydrolysed, the substance reduces Fehling's solution. It is about 150 times sweeter than sugar. *Rebaudin* is insoluble in absolute alcohol, and leaves 10–11 per cent. of ash on ignition. It is probably a glucoside; contains no nitrogen and melts at about 107° C. It is 10 times sweeter than sugar. At present the plant is difficult to procure, otherwise it would be of considerable practical use. The author suggests the use of the dried and powdered leaves as a sweetening agent.—F. SHOX.

Alkaloid extracts; Analysis and evaluation of — [for medicinal purposes]. M. Hamburg. Seventh Int. Congr. Appl. Chem., London, 1909.

The value of a malt extract for dietetic or medicinal purposes depends mainly on its enzymatic activity and its purity. The enzymatic activity should be determined from the quantity of maltose formed by the action of the extract on starch paste at the temperature of the body, the relation between extract and starch being chosen so as to give about a 1 per cent. solution of maltose. The detection of adulterants in malt extract is difficult, in the presence of glucose or starch syrup may be rendered evident by determining the non-reducing, nitrogen-free extract. This is given by the dry substance of the extract, less the sum of the reducing sugars calculated as maltose and the nitrogenous substances (nitrogen 6.25). The number thus obtained should lie between 2 and 20.74 per cent. of the dry substance. If the non-reducing, nitrogen-free extract is less than 8.2, adulteration with material containing monosaccharide is certain, whilst higher value than 20.74 indicates addition of cane or beet sugar molasses.—T. H. P.

Elaterin. A. Berg. Seventh Int. Congr. Appl. Chem., London, 1909.

The author considers that elaterin is not present in the free state in the fruit of *Echallium elaterium*, but is liberated by the action of an enzyme, *elaterase*, from an amorphous glucoside. The author still retains the formula, $C_{28}H_{38}O_7$. The molecule of elaterin contains two phenolic hydroxyls, an acetyl grouping, a keto grouping, and possibly a lactone ring. (See this J., 1907, 113.)—F. SHOX.

Asiphyl [mercuric *p*-aminophenylarsonate]. E. Mameli and G. Chiffo. Seventh Int. Congr. Appl. Chem., London, 1909.

The authors have prepared the mercuric salt of *p*-aminophenylarsonic acid, $[NH_2 \cdot C_6H_4 \cdot AsO(OH)O]_2Hg$, to which they have given the name, *asiphyl*. In this new compound the therapeutic action of atoxyl (sodium *p*-aminophenylarsonate) and of mercury are combined, and it is of value in the treatment of syphilis.—A. S.

Catalytic reactions at high temperatures and pressures. W. I. Ipatiew. Seventh Int. Congr. Appl. Chem., London, 1909. (See also Ber., 1909, 42, 2089–2097).

ETHYLENIC hydrocarbons and aliphatic acids containing a double linkage can readily be hydrogenised in a high-pressure apparatus in presence of copper oxide as a catalyst. Amylene and trimethylethylene yield isopentane; ethylene and propylene yield ethane and propane respectively; sodium oleate is reduced to sodium stearate. Aromatic acids can also be hydrogenised under high pressure; cinnamic acid yields cyclohexylbutyric acid with nickel oxide as catalyst, and hydrocinnamic acid when copper oxide is used; with reduced copper the hydrogenisation is not complete. β -Naphthoic acid yields first tetrahydronaphthoic acid and then decahydronaphthoic acid. α -Naphthoic acid yields tetrahydronaphthalene. Fluorene, acenaphthene, and retene, when hydrogenised in presence of nickel oxide as catalyst, yield perhydrofluorene ($C_{13}H_{22}$, b.p. 254–258° C.), perhydroacenaphthene ($C_{12}H_{20}$, b.p. 234–240° C.), and perhydroretene ($C_{17}H_{32}$, b.p. 300–310° C.) respectively. Perhydroretene is an isomeride of, but not identical with, the hydrocarbon fichtellite.—A. S.

Surrender of Letters Patent under the Patents and Designs Act, 1907. London Gazette, July 9, 1909.

ALBERT KNOLL, Max Daeger, and Hans Knoll have offered to surrender the Letters Patent No. 17,511 of 1905 (see this J., 1906, 233), granted for an invention for "Manufacture of santalol esters from sandal wood oil," of which they are the registered owners. Any person who desires to be heard with reference to such surrender should notify his desire to the Comptroller-General, at the Patent Office, 25, Southampton Buildings, London, W.C., on or before August 9, 1909.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Autochrome plates; Simplified treatment of —, and correction of errors of exposure during development. A. and L. Lumière and A. Seyewetz. Seventh Int. Cong. Appl. Chem., London, 1909.

AUTOCHROME plates which have been correctly exposed may be developed by using only three operations, *viz.*, a development with metoquinone and ammonia, reversal with an acid solution of permanganate, and a second development similar to the first. If there is doubt as to the correctness of the exposure, the plate is immersed in a diluted developer, and the time necessary for the appearance of the image noted; a further quantity of developer is then added, and development continued for a time which is found from a table.—T. F. B.

Photographic plates; Different effects of sensitisers on — according to the properties of the emulsified silver bromide. S. de Prokondine-Gorsky. Seventh Int. Cong. Appl. Chem., London, 1909.

THE silver bromide in each brand of photographic plate possesses special properties of its own as regards its sensitiveness to coloured light rays. Only those plates whose emulsions, without preliminary treatment, are distinctly sensitive to all parts of the spectrum, can be rendered panchromatic; in order to obtain a high degree of sensitiveness for a particular portion of the spectrum, plates should be used which, before treatment, are as sensitive as possible to that portion, even if the emulsion is not otherwise sufficiently sensitive.—T. F. B.

Eder's solution. [Detection of ferrous salts and of oxygen]. C. Winther. Seventh Int. Cong. Appl. Chem., London, 1909.

DECOMPOSITION of Eder's solution by light is accelerated by adding ferric chloride up to a certain point, when further addition decreases the sensitiveness; the presence of oxygen intensifies the action of the ferric chloride. This action is due to the formation of ferrous oxalate by the action of ferric chloride on ammonium oxalate in absence of light. Ferrous oxalate precipitates far more than its equivalent of mercurous chloride from Eder's solution, especially in absence of air. In presence of a ferric salt, this precipitation is slower, and increases when the amount of oxygen in the solution is decreased. The decomposition of Eder's solution in light is therefore due to the presence of traces of iron salts; when free from

iron salts it is insensitive to light. The precipitation of mercurous chloride by ferrous salts may be used as a delicate test for ferrous salts and for oxygen.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Nitration of cotton. C. Piest. Z. angew. Chem., 1909, 22, 1215—1224.

BEIL and Klays (this J., 1907, 1157) and Beil (Z. ges. Schiess- u. Sprengstoffw., 1909, 81) have studied the influence of the previous treatment of the cellulose on the properties of the resulting nitro-compounds, but their experiments were apparently under laboratory conditions. The author has, therefore, made similar experiments, but working with larger quantities according to the usual technical methods. The cotton was subjected to the following treatments:—(1), Bleaching for 48 hours in bleaching powder solution of 3.5° B.; (2) and (3) bleaching for 8 days in solutions prepared by mixing 2.5 and 5 kilos, respectively of bleaching powder with 5 litres of water; (4), mercerisation by treatment with 18.5 per cent. caustic soda lye for 20 minutes; (5), heating for 10 hours at 150° C. in a current of carbon dioxide (see Ger. Pat. 199,885; this J., 1908, 937). The results obtained showed that with a given nitrating acid and temperature of nitration, the nitrocellulose prepared from strongly bleached cotton has a somewhat lower nitrogen-content, and a considerably higher solubility in ether-alcohol, than that prepared from ordinary cotton. The solubility of the nitro-compound in absolute alcohol increases as the cotton is more strongly bleached. Nitrocellulose from strongly bleached cotton is more difficult to stabilise than that from ordinary cotton. The stabilised nitrocellulose is more soluble in ether-alcohol than the non-stabilised product. Nitrocellulose from mercerised cotton has a slightly lower nitrogen-content, a much higher solubility in ether-alcohol, about the same solubility in absolute alcohol, and is more difficult to stabilise than that from ordinary cotton. Nitrocellulose prepared from cotton which has been heated in a current of carbon dioxide has a slightly higher nitrogen-content, about the same solubility in absolute alcohol and in ether-alcohol, and is more difficult to stabilise than that from ordinary cotton.—A. S.

Trinitrotoluene factory; Explosion in the Schönbeck-on-Elbe — J. Rudeloff. Z. ges. Schiess- und Sprengstoffwesen, 1909, 4, 213—214.

THE explosion took place in that part of the factory where the impure trinitrotoluene was recrystallised from alcohol. Centrifugal machines, and an inclined drying cylinder, heated by a hot water jacket, were used for freeing the crystals from alcohol. It seems probable that a fire originated in one of the centrifugals and spread to the drying machine, where an explosion of alcoholic vapour and air resulted, the force of which was probably increased by the presence of trinitrotoluene dust in suspension in the explosive mixture. The fire in the centrifugal may have originated from an overheated bearing or a too severe use of the brake apparatus. On a former occasion a fire had originated in a similar manner owing to a workman using a large wooden paddle (intended for emptying the centrifugal) as a brake on the rim of the basket. The drying machine contained 400 kilos of trinitrotoluene, and this could not have exploded if the damage would have been more extensive. Th

flowing facts show that trinitrotoluene may be present in a very severe conflagration without exploding. There were 100 kilos. of trinitrotoluene in a sieve below the drying machine, 1000 kilos. in a packing house adjoining, and very considerable quantities in tinplate receptacles. In all cases the material burnt away without exploding even though in the last case the containing vessels were melted, and the walls of the building showed that there had been an extremely high temperature. Three very large vessels containing trinitrotoluene dissolved in alcohol continued to burn for about three days without exploding. Finally a trinitrotoluene explosive, "trinitrite," in cartridges and loose in large vessels, also burnt off quietly.—G. W. McD.

Explosion of detonators; Circumstances attending an explosion which occurred at the factory of The Cotton Powder Co., Ltd., at Uples Marshes, Faversham, Kent, on April 1, 1909. Major T. H. Crozier, H.M. Inspector of Explosives. [Cd. 4693.]

The operation in progress at the time of the explosion was the filling of copper detonator shells with fulminate composition which consists of a mixture of mercury fulminate, potassium chlorate and gun-cotton dust. A "jig" or holder for 100 detonator shells, each containing 1 gm. of composition was in use at the time of the explosion. I also used a vulcanite measuring plate, for the composition, which fitted on top of the jig. The object of the plate, constructed of brass and vulcanite, was to keep the detonator shells vertical during filling. A little over 1/2 gm. of composition, containing 2.85 per cent. of moisture, was in the compartment. The effects of the explosion, as always the case with a fulminate composition, were extremely local. Major Crozier concludes that there were two separate explosions—one on the work-table and the other on an adjacent shelf—and that the initial explosion occurred at the work-table. From the observed facts it was evident that the composition was already in the detonator shells and that the measuring plate had not been removed from the top, since it was also blown into fragments. It is possible that the workman having lifted the measuring plate a few inches, accidentally let it fall back on to the jig, and the impact caused the explosion of composition dust which would be the surface of the jig. On the other hand, the whole might have been lifted and tapped upon the india-rubber pad, for the purpose of shaking down the composition into the detonator shells, thereby jarring the plates together. The explosion could have been brought out by the impact of the plates in either manner suggested above, seeing that detonator composition is extremely sensitive to a blow or to friction. It is also considered that the slots in the jig plate, in which the plates of the measuring plate worked, are a source of danger, as any composition lodging in them would dry quickly and might receive a blow from one of the pins. It is worthy of note that this was the first recorded accident at the factory for some 30 years, during this particular operation in the manufacture of detonators. It is suggested that the apparatus should be arranged in such a manner that the operation of moving the measuring plate, tapping the jig and removing the measuring plate could be performed from behind an efficient screen.

—G. W. McD.

Cellulose; The theory of the nitration of cellulose. — M. A. Saposchnikow. Seventh Int. Congr. Appl. Chem., London, 1909.

The general scientific theory connecting the composition of the mixed acids and the degree of nitration of cellulose has been enunciated. The difficulties in the way of such generalisation are as follows: The molecular weights of cellulose and the cellulose nitrates are unknown. No direct cellulose nitrates corresponding to any particular formula are known, seeing that products of all intermediate degrees of nitration can be prepared. The system of acid nature and nitrocellulose is not homogeneous and cannot be treated from the point of view of the law of mass action. Considering the mixed acids with respect to the molecular proportions of sulphuric acid, nitric acid, and water, the

author has in previous work embodied his results in a series of curves, connecting the vapour tension of nitric acid in the mixed acids with the composition of the acid (see this J., 1907, 34). In a second series of experiments (*loc. cit.*) he has shown the relationship of the degree of nitration obtained with mixed acids, under similar conditions, i.e., the molecular proportions of the ingredients present in the mixed acid. In the present communication these two series of curves have been combined by employing the method of co-ordinate triangles, and in this way a clear idea is obtained of the conditions governing any desired degree of nitration. Actual results of nitration show a very close agreement with the results to be anticipated from the theoretical standpoint.—G. W. McD.

Explosives; Detection of mercury in explosives. — G. W. Patterson. Seventh Int. Congr. Appl. Chem., London, 1909.

SIMPLIFIED methods of preparation for spectroscopic tests are described. Two grm. samples are dissolved in organic solvents and electrolysed directly in the solvent, or, when only partly soluble, extracted by such solvents, and the residue treated with nitric acid to destroy all organic material, the residue being extracted with water and electrolysed. Metallic mercury is detected by the modified or second method. The method is also applicable for separation for quantitative determinations. The method is accurate to 0.000001 grm. of mercury, but fails with less than 0.0000001 grm. of mercury.

Smokeless powder; Stability tests of smokeless powder. — G. W. Patterson. Seventh Int. Congr. Appl. Chem., London, 1909.

As regards tests of single base powders, the author regards the German test at 135° C. as the most suitable high temperature test, and the surveillance test at 65.5° C. and Vieille test at 108.5° C. as the most suitable low temperature tests, the latter requiring more labour and care in operation.

Explosives; Method of investigating the sensitiveness of explosives to shock by a falling weight. H. Kast. Seventh Int. Congr. Appl. Chem., London, 1909.

For some years past, at the Military Research Laboratory in Berlin, an apparatus and method have been used with very satisfactory results for determining the sensitiveness to shock of explosives. The apparatus itself consists of two well-turned steel pistons, with heads, and a broad steel ring with a hole through the centre into which the pistons fit perfectly. The method of carrying out the experiment is as follows: The shorter of the two pistons is placed with its head upon an anvil and clamped in position. The steel ring is slipped over this piston and only passes so far that a cup is left. The explosive to be tested is placed in this cup and the other piston placed in position on top. The explosive is thus contained between two circular surfaces each of an area of 0.5 sq. cm. A known weight is then allowed to fall from varying heights upon the head of the upper piston, and the result is observed, from point of view of sensitiveness to shock. The advantages claimed for this apparatus are, that it works very well; that the various parts are easily made interchangeable, and that it can be very easily and rapidly cleaned from any residue of unexploded material. Owing to the form of the apparatus, the frictional play between the two surfaces is reduced to a minimum, and it is the sensitiveness to shock alone which is actually determined. As regards the apparatus itself, it is pointed out that the hole in the steel ring and the pistons themselves should be made with great exactitude, so as to fit perfectly without either loose play or too much friction. The pistons should be so tempered that they are neither distorted nor fractured by the blow. The surface of contact between the two pistons should be quite polished. In using the apparatus it is suggested that at least six determinations should be made and that three different sets of apparatus should be used so as to eliminate as much as possible any slight defects in a single apparatus. The temperature of experiment should be between 15° and 20° C., and should an apparatus become warm by use, it ought to be cooled down to this temperature before

being employed again. From experiments the author states that even with explosives which are fairly non-sensitive the following are the maximum heights which would be required to bring about explosion:—For 2 kilos., 60 cm.; 5 kilos., 30 cm.; 10 kilos., 24 cm.; 20 kilos., 20 cm. It is pointed out that the results of the experiments should be differentiated as follows:—(1). No explosion. (2). Feeble explosion; with appearance of smoke, a smell of burning, and no audible sound. (3). Feeble explosion. (4). Strong explosion. (5). Violent explosion. In the author's experience about 0.04 grm. is usually found to be sufficient for each experiment, and this amount can be easily measured out in a small cap.—G. W. McD.

Explosion of firedamp and coal dust: Experiments with explosives in regard to the —. Mente and W. Will. Seventh Int. Congr. Appl. Chem., London, 1909.

An account is given of the experimental methods adopted in various countries for the purpose of testing the suitability of explosives, from the point of view of safety, in coal mines where firedamp and coal dust may be present. All countries adopt some form of gallery containing an explosive mixture into which a shot is fired, with or without stemming. The United States employ a circular iron gallery, 1.93 m. diameter and 30.5 m. long. The shot is fired with or without stemming into an explosive mixture of pit gas or into coal dust. In France a gallery was first erected at Lens, but recently this work has been carried out at Liévin where an experimental gallery of 65 m. was erected, which was later increased to 500 m., with drives and other additions intended to represent as nearly as possible the actual conditions of mining. Arrangements are also made for experimenting with coal dust, and the use of ventilating plant brings experimental conditions closely in touch with actual work. The Belgian testing station at the Frameries has a gallery of elliptical section of 2 sq. m. area, and a length of 30 m. An explosive mixture containing 8 per cent. of pit gas mixed with air is used. Coal dust is also employed. Shots are fired without stemming, and a "charge limite" is determined which will not under these conditions ignite the explosive mixture. In England the testing station at Woolwich employs a gallery of circular section 0.7 m. in diameter and 9 m. in length. The explosive mixture consists of 15 per cent. of coal gas and 85 per cent. of air. Coal dust has not up to the present been officially used in the test, but the Royal Commission on Safety in Mines has the subject under review. The charge to be used was originally determined as that which gave in the Trauzl lead block the same expansion as 56 grms. of dynamite No. 1 (75 per cent. of nitroglycerin). In 1903 the ballistic pendulum test for determining the weight of charge supplanted the lead block test. Ten shots, using 30 cm. of special dry clay as stemming, and another 10 shots using only 23 cm. of stemming, have to be fired into the explosive mixture without either igniting it or leaving any perceptible amount of unconsumed explosive. A large testing station has recently been built in England, at Alchotts, of circular section, 2.3 m. in diameter and 213.5 m. in length. The question of the effect of coal dust and its influence in propagating explosions will be studied, and also questions of ventilation. In Austria-Hungary galleries were erected at Mährisch-Ostrau and Segen-Gottes in 1886. Shots were fired into a mixture of pit gas and air or into coal dust. The explosive was fired, not from a mortar, as is the general usage, but from a cartridge case which stood on a lead block in the gallery. The extent of the compression of the lead block gave an indication of the strength of the explosive. More recently at Rossitz a gallery 300 m. long has been in operation, where experiments on a practical scale are carried out. In Germany there are 5 official testing stations. The best known is at Gelsenkirchen where an elliptical gallery, 2 sq. m. in cross-section area and 35 m. in length, is used. Natural pit gas is employed and also coal-dust. It is now proposed to erect a large gallery in which experiments can be carried out [simulating actual] mining conditions. Every coal-getting country of any importance has, it will be noted, erected testing stations for the proof of the comparative safety of mining explosives in use. In

most cases galleries of considerable diameter but short lengths are employed, but a tendency towards proof in large galleries under working conditions is very evident. The authors draw attention to the many points awaiting definite solution, such as the effects of artificial and natural gas in the galleries, the presence of coal dust, the size of the cartridge and the bore hole, the atmospheric temperature and pressure, etc. Seeing the enormous importance of the subject of safety explosives, a plea is put forward for the international consideration of question of such vital interest.—G. W. McD.

PATENTS.

Explosive. E. A. Le Sueur, Ottawa, Canada. U.S. Pat. 923,435, June 1, 1909.

The explosive is prepared by mixing together saltpetre sulphur, and a substance containing hydrocarbons, and a wax, converting the mixture into grains, and coating the grains with powdered potassium chlorate.—J. H. J.

Dinitroglycerin obtained from glycerin and nitric acid
Process for the separation of —. Castropser Siebel'sche Sprengstoff-Akt.-Ges. Ger. Pat. 210,558, Jan. 24 1908.

AFTER nitration, the reaction product is neutralised with ammonium carbonate, and the dinitroglycerin while separates is removed. The aqueous solution is concentrated in order to recover the greater part of the ammonium nitrate by crystallisation, and the residual liquid is shaken with the dinitroglycerin separated in the first part of the process, this latter acting, it is stated, as a solvent for the mono- and di-nitroglycerin remaining dissolved in the solution after separation of the ammonium nitrate.—A. I.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Mercury joint instead of cork or rubber for connecting the combustion tube with the calcium chloride tube. J. Marek. J. prakt. Chem., 1909, 79, 510—512.

THE author has simplified the mercury joint previously described (this J., 1907, 992). The end of the combustion tube is bent upwards at right angles as shown in the figure and round this is fixed, by means of a cork protected underneath by an asbestos sheet, a short glass tube to contain the mercury. Over the end of the combustion tube is placed the conical end of the calcium chloride tube which is fitted with a ground-in hollow glass stopper (not shown in the figure). During the combustion a thermometer is placed in the mercury which should have a temperature of 60°—70° C. in order to prevent the condensation of water in the end of the combustion tube. During the combustion also, the whole mercury joint should be supported with an asbestos sheet so as not to bend the tube.—J. C. C.

PATENT.

Density: Apparatus for determining —. W. D. Mour. Assignor to The Mathieson Alkali Works, Saltville Va. U.S. Pat. 923,560, June 1, 1909.

The density of a powdered or granular material is determined by putting a weighed quantity into a vessel

linder and placing a closely fitting plunger above it. The cylinder is then tapped or jarred by a magnetic shaking apparatus and when the material has been shaken together so that it occupies the smallest space, the volume indicated by the distance between the bottom of the plunger and the bottom of the cylinder. This is read off on a graduated rod which extends upwards from the plunger.—W. H. C.

INORGANIC—QUALITATIVE.

For zinc salts; Colour reaction for —. A. del Campo Cerdan. Ann. Chim. analyt., 1909, 14, 205—206.

To a solution of a zinc salt sufficient ammonia be added to re-dissolve the precipitate at first formed, and then a c.c. of an alcoholic or ethereal solution of resorcinol. The blue colour is developed more or less rapidly according to the amount of zinc present. By this reaction 0.1 gm. of zinc may be detected in 1 litre of solution. For very small quantities of zinc, an ethereal solution of resorcinol is more sensitive than an alcoholic one. In ammonium, under like conditions, gives a green colour, which may mask the zinc reaction if only traces of the latter metal be present; and nickel, besides giving a blue colour with ammonia alone, gradually gives a tint to the resorcinol solution resembling that afforded by zinc. Cobalt gives the red colour distinctive of the cobalt-nickel. Copper, manganese, and certain oxidising substances, and reducing agents affect the reaction. These substances must therefore be removed before applying the test.—J. O. B.

For cobalt; New microchemical reaction for —. [Nickel and cobalt dimethylaminobenzene-azobenzene-sulphonates.] M. E. Pozzi-Escot. Ann. Chim. Analyt., 1909, 14, 207—208.

METHYLAMINOBENZENE-AZOBENZENESULPHONIC acid gives a number of sparingly soluble precipitates with metallic salts, the crystalline forms of which are very characteristic and distinctive. The nickel salt is a yellowish and amorphous precipitate in the cold; it re-dissolves on warming with a large volume of water, forming yellow, hexagonal tablets as the solution cools. Magnesium behaves similarly, but the precipitate assumes the crystalline form almost at once, in the cold, and moreover, the crystals are much smaller than those of the nickel compound. Cobalt gives a crystalline precipitate from both hot and cold solutions, composed of long slender white or blackish needles, often arranged in a stellate form. From rapid crystallisations, very minute needles appear in palse form, are obtained. This reaction is very distinctive and is not affected by the presence of nickel. Thallium, cerium, aluminium, manganese, sodium, chromium and silver, are also precipitated in somewhat similar manner; but the large size and distinctive colour of the cobalt crystals, enables them to be at once distinguished from these.—J. O. B.

For iron's solution. [Detection of ferrous salts and of oxygen.] Winther. See XXI.

INORGANIC—QUANTITATIVE.

For nickel; Determination of — in the presence of cobalt. J. A. Sanchez. Bull. Soc. Chim., 1909, 5, 641—647.

Potassium cyanide is added to a neutral solution containing nickel and cobalt, until the precipitate formed is redissolved, and the solution is evaporated to dryness in contact with air, the cobaltocyanide, $K_3Co(CN)_6$, is converted to cobaltic cyanide, $K_3Co_2(CN)_{12}$, whereas the nickel compound is unaffected, and, on addition of silver nitrate, insoluble silver cobaltic cyanide and cyanide are precipitated, and the nickel is left in solution as nitrate. This means very small amounts of nickel may be readily detected and estimated in the presence of large quantities of cobalt. For the determination of nickel, enough of a 10 per cent. solution of potassium cyanide is added from a burette to the neutral solution, containing only cobalt and nickel, to dissolve the precipitate first formed, the solution is evaporated to dryness on the water-bath, and the residue dissolved in 20 c.c. of hot

water; then excess of a 10 per cent. solution of silver nitrate is added (10 times the volume of the potassium cyanide used), and, after heating and stirring, the precipitate is washed by decantation with boiling water; the excess of silver is precipitated from the liquid and washings by adding a 14 per cent. solution of potassium bromide, and the filtrate from this is made up to 300 c.c. with hot water, being then rendered alkaline with caustic alkali, and the nickel hydroxide converted into hydrated sesquioxide by treatment with bromine water; after boiling for 10—15 minutes, the oxide is filtered off and washed with boiling water, and the determination then finished gravimetrically or better as follows:—The precipitate and filter are transferred to a flask with about 20 c.c. of water at 60°—70° C., and 5 c.c. of a 20 per cent. solution of potassium iodide and 5 c.c. of a 20 per cent. solution of sulphuric acid are added; then the liberated iodine is titrated with $N/100$ thiosulphate at the same temperature, every c.c. of thiosulphate being equivalent to 0.000586 gm. of nickel. If it be desired to determine both metals, they may be precipitated together as sesquioxides by means of caustic alkali and bromine water, and then, after weighing the oxides, they may be dissolved and the nickel determined as above.

—F. SODX.

Traces of silver; Determination of —, and the solubility of some "insoluble" silver salts. G. S. Whitby. Seventh Int. Congr. Appl. Chem., London, 1909.

WHILST investigating a method for preparing a colloidal solution of silver, it was found that solutions of silver salts when heated with a little sodium hydroxide and certain organic bodies develop a brown or yellow colour, even when the amount of silver present is very minute. 50 c.c. of a solution containing one part of silver in 25 million parts of solution gave a recognisable colour. It has also been found possible to apply this method to the quantitative determination of traces of silver. The organic substances which have hitherto been found capable of giving this colour when heated with silver solutions containing a little sodium hydroxide are dextrin, gum arabic, glycerol, cellulose (in the shape of filter paper), starch and sucrose, but the last of these is most suitable for the determination of small quantities of silver. To 50 c.c. of the silver solution, appropriately diluted, are added a few drops of a fairly concentrated solution of sucrose, and the beaker containing the liquid is immersed in a bath of boiling water for two minutes. About 6 drops of a $N/1$ solution of sodium hydroxide are added, and the heating is continued for not more than two minutes until the colour develops. The solution is cooled, transferred to a Nessler glass, and the colour compared with that of a standard. The standard colours are prepared from silver nitrate solutions of known strength, and are most conveniently of such strengths that 1 c.c. equals 0.000001 gm. of silver, and 1 c.c. equals 0.0000005 gm. of silver. The standard should not be prepared more than 12 hours before the actual experiment, since the colour deepens somewhat on standing. The colour produced by these minute amounts of silver is due to the presence of colloidal silver. The solutions give the Tyndall effect, and display the other characteristics of colloidal solutions of silver. The method is being applied to the determination of the solubility of sparingly soluble silver salts, particularly with reference to the conditions that arise in analytical work. Thus, at 21° C. the amount of freshly-prepared floccular silver chloride dissolved by a litre of water was found to be 1.55 mgrms.; a result which confirms the values obtained by Kohlrausch and Rose, and by Böttger.

ORGANIC—QUANTITATIVE.

Boiling-point determinations under diminished pressure: A rarely observed source of error in —. C. von Reichenberg. J. prakt. Chem., 1909, 79, 475–491.

THE author points out that the usual arrangement of an apparatus for distilling under diminished pressure, in which the manometer is connected to the receiver, leads to erroneous figures as, owing to the distance of the manometer from the distilling flask and the throttling of the vapours in the narrow side-tube of the latter, the true pressure of the vapour, at the temperature given by the thermometer in the flask, is really several mm. higher than that recorded. This difference varies with the speed of distillation and the size of the side-tube of the distilling flask. In order to ascertain the true pressure under which the liquid distils, it is necessary to attach a manometer directly to the distilling flask by means of an extra side-tube. The author shows that many of the observations of pressure, made in the usual apparatus, cannot be regarded as correct.—J. C. C.

Sulphur; Determination of — by the catalytic method. G. Maderna. Seventh Int. Congr. Appl. Chem., London, 1909.

BRUCKER'S method (this J., 1905, 1086), which depends upon the catalytic action of cobalt oxide, can be applied successfully to the determination of sulphur in pyrites and in bitumens. Nickel oxide may be substituted for cobalt oxide and presents certain advantages over the latter. Of the methods hitherto proposed for the determination of sulphur in bitumens, only a modification of Eschka's method and Henriques' method have proved useful, and these are not always applicable. The catalytic method besides being more accurate, also occupies much less time than the two processes mentioned.—A. S.

XXIV.—SCIENTIFIC & TECHNICAL NOTES

Solubility of gases in water; Influence of colloids on colloid suspensions on the —. A. Findlay and H. J. M. Creighton. Seventh Int. Congr. Appl. Chem. London, 1909.

IS a preliminary note on the above subject, which is of essential importance in connection with the absorptive of gases by blood, it has been pointed out that absorption of carbon dioxide by water, under atmospheric pressure is increased, is unaffected, or is decreased by the presence of colloids and suspensions, according to the nature of the colloids present. This result pointed to the increase of absorption of carbon dioxide in presence of ferric hydroxide, gelatin, etc., as being due to chemical combination. As was pointed out in the preliminary note, however, the variation of absorption with pressure is of great importance for giving an insight into the influence of colloids than the change of absorption at any one pressure. Moreover, by studying the absorption of a neutral gas such as nitrous oxide, the effect due to chemical combination would be excluded. Experiments on these lines have been carried out during the past winter, the influence of ferric hydroxide, gelatin, arsenious sulphide, silicic acid, dextrin, starch, glycogen, egg albumin, and serum albumin, as well as suspensions of charcoal and silica on the absorption of carbon dioxide and of nitrous oxide having been investigated, at pressures varying from about 750 mm. to 1400 mm. of mercury. The chief factors which may be expected to influence the position and course of the absorption curves in presence of colloid relatively to the absorption curve in pure water (which is a horizontal line, according to Henry's law) are chemical combination, tending to raise the curve above that for water; presence of substance in true solution tending to lower the solubility; adsorption, accompanied or unaccompanied by solution of the gas in the colloid.

terial, tending to increase the solubility. Although we have not yet completely analysed the solubility curves which we have obtained, the following results may be given. Except in the case of suspensions of arsenious sulphide, the solubility curves obtained are, in general, similar in form. As the pressure is increased, the solubility increases but slightly, or may even slightly fall, but afterwards increases, although not proportionally with the pressure. This increase in solubility with pressure is more marked with nitrous oxide than with carbon dioxide, and from the data obtained, it has been concluded that an increase of solubility is due to adsorption. In the case of ferric hydroxide and gelatin, the solubility curve for carbon dioxide lies above that for the solubility in pure water, and this may be ascribed to chemical combination, and in the case of nitrous oxide, this increase in solubility is not observed. In other cases the solubility of the gases is diminished, a behaviour which at present can be most readily explained by the assumption of adsorption of the colloids.

Viscosity of solutions, and its bearing on the nature of solution. A. E. Dunstan. Seventh Int. Congr. Appl. Chem., London, 1909.

The author develops the following experimental laws:—
(1) When two monomolecular liquids are mixed, the viscosity of the mixtures only approximates to that demanded by the law of mixtures. The greater the divergence from this law, the greater is the mutual effect, η , of association, of the one on the other.

(2) In the case premised in (1) there exists a relationship between the angles made by tangents to the origins of the curves, and the respective molecular weights of the component liquids.

(3) When associated liquids are mixed, the viscosity of the mixture may attain a maximum value, which is held to indicate association, since it is well known that highly associated liquids are more viscous than simple liquids. These maxima invariably correspond with points of simple molecular concentration. (4) In the case premised in (1) the viscosity of the mixture may attain a minimum. On the same lines of reasoning, this implies a mutual association. (5) For pure substances the relationship $\eta = a + b \log M$, wt. is found to be universally applicable.

(6) For pure substances the relationship $\frac{\eta}{\text{Mol. Vol.}} \times 10^6$

is good for each chemical (homologues) series. The knowledge thus obtained has been applied to the following cases:—

- The condition of aqueous solution of sulphur trioxide.
- The existence of racemic compounds in solution.
- Various cases of isomeric change.
- The stability of hydrates in solution. Although little has been done at present from a technical point of view, yet the simplicity of the method and its remarkable sensitiveness render it most valuable in cases where knowledge of the condition of molecular aggregation is needed. To mention one example only, it has recently been applied to the determination of the "nerve" of India-rubber with good results.

Absorption ("Sorption") of hydrogen by carbon: Mechanism of the —. J. W. McBain. Seventh Int. Congr. Appl. Chem., London, 1909.

ABSORPTION is quite variously regarded by various authorities as one of the following:—(1.) True chemical combination. (2.) True solid solution. (3.) A modified solid solution in which practically only the outer layers become saturated owing to the difficulty of diffusion in solids. (4.) Condensation on the outside of the surface of the solid.

The first three are contrary to the requirements of thermodynamic theory, and the fundamental assumption of the third is disproved by experiments in which the time required for adsorption of hydrogen by carbon was independent of the pressure of hydrogen to be adsorbed. The fourth is found insufficient to explain the somewhat complex time relationships studied here, which, however, point strikingly to the conclusion that both true solid solution (true diffusion) and surface condensation occur.

They are independent of each other and their relative importance and magnitude depend upon the conditions of the experiment. The non-committal name "sorption" is coined to designate the sum total of the phenomena, while "adsorption" and "desorption" are restricted to the dissolved and superficially condensed matter respectively. It is found that the surface condensation requires only a few minutes for completion, whereas adsorption requires, in the case of hydrogen diffusing into carbon at the temperature of liquid air, a dozen hours for practical completion. Thus it was possible to isolate the two phenomena and to study them more or less independently of each other. For instance, by suitable manipulation a sample of carbon can be prepared highly charged with hydrogen in a state of solid solution but almost destitute of adsorbed hydrogen condensed on the surface. This is clearly attainable (if the hypothesis be correct) by suddenly exposing to a vacuum, carbon which has been previously saturated by long contact with hydrogen at a constant temperature. Such carbon, exposed to a low pressure of hydrogen and cut off from all external influences, took up hydrogen at first (surface condensation) although already supersaturated (*i.e.*, in respect to the solid solution), and then gave it off again in still greater quantity until final equilibrium was established. Thus the manometer first fell for a few minutes and then rose to a higher point than the initial value. In the converse case, where the interior was free from hydrogen but the surface had become supersaturated by a very short exposure to a high pressure of gas, hydrogen was first given off, and then taken up again by diffusion into carbon. Here the manometer automatically rose for a few minutes, then steadily fell for many hours to a lower value than previously obtained. The pressure changes observed, might at first seem unimportant, were it not for the one fact of great significance, *viz.*, that (taking the second case just outlined) the higher pressure at five minutes was even less than corresponded to the gas condensed on the surface of the carbon, and yet after a dozen hours had elapsed a much lower pressure was attained, a pressure which then actually did correspond to the condensed gas in equilibrium with it. Thus a considerable body of hydrogen had been transferred from this surface to the interior of the carbon. An approximate calculation of the extent of this transfer showed that the true solubility of hydrogen at the temperature of liquid air and under 2 cm. pressure was at least 4 c.c. (corr.) per gram of the coconut carbon employed. This absorption was roughly proportional to the square root of the pressure (whereas the total sorption varies as the cube root of the pressure). From this it appears that the dissolved hydrogen is split up into single atoms.

Trade Report.

Factories and Workshops: Annual Report for 1908. Home Office, 1909 [Cl. 4661]. Price 2s. 4d.

THE general report deals only with certain of the broader issues bearing upon the work of the Department: a summary of the sectional reports (including Industrial Poisoning and Dangerous Trades) and a general index are given at the end of it.

White phosphorus matches.—As the outcome of the Berne Conferences of 1905 and 1906, certain European countries decided to prohibit the use of white phosphorus, but the United Kingdom, Sweden, Norway, and Belgium did not see their way to similar action. Further regulations, proposed by the Home Office, were held by manufacturers to be oppressive; for three years no case of necrosis had appeared, save at one factory. Meanwhile, Departmental investigations, made in 1907, showed the need of more stringent dental examination and treatment, and the substitution of automatic machines for hand labour; and it was ascertained that "strike anywhere" matches could be made without white phosphorus, though patent rights, both in materials and machines, stood in the way of universal adoption. In 1908, match manufacturers

and the holders of patent rights in phosphorus substitutes agreed in favour of the prohibition of white phosphorus, provided that importation of white phosphorus matches were prohibited, and that the Home Office settled binding terms by which anyone might use the patented substitutes. This solution was accepted by the Home Office, and accordingly the White Phosphorus Matches Prohibition Act was passed, which comes into force on Jan. 1st, 1910 (this J., 1909, 43). Meanwhile all the match factories, save one, remained free from necrosis, but in this one a further case occurred in 1908, and two more cases in the first quarter of 1909. The disuse of white phosphorus renders the Special Rules of 1899 obsolete, but care will have to be taken in using phosphorus sesquisulphide, one of the substitutes, though it entails no risk like that attending the use of white phosphorus.

The following statistics of imports and exports of matches in 1907, distinguishing between "safety" matches (without white phosphorus), and "strike anywhere" matches (which as a rule contain it) are of interest. The unit is a gross of boxes.

Origin or destination.	"Safety" matches.	"Strike anywhere" matches.

Regulations.—The Regulations for enamelling of metal and of glass, and for benzene derivatives were settled by discussion with the trade without recourse to public inquiry, and the latter came into force: the timing of metals with use of lead was certified to be a dangerous trade; seven codes of Special Rules are being superseded by Regulations of automatic application as the outcome of action now taken, and seven others have been so dealt with in earlier years. There remain nine codes of Special Rules to be converted into Regulations of automatic application: white lead, red and orange lead, yellow lead, lead smelting, hides and skins, bichromate, vulcanising of india rubber and carbon disulphide, chemical works, and bottling of aerated waters.

Potteries.—In a few potteries, out of 563 under Special Rules, there is a limitation of the use of lead in glaze, as a condition of the relaxation of certain rules, but only one case of lead poisoning, attributable to glaze, has been reported since 1905. The "leadless" (*i.e.*, 1 per cent.) Rule 22 has been in force since 1902 in 17 potteries and parts of 12 others, without any known instance of poisoning. Samples of glaze have been taken at intervals, and some excess has been found in four instances out of 124. There are two potteries in which a 2 per cent. limit is in force under Rule 24. In one of these, four cases of poisoning had occurred in 1906, and one in 1907. The 2 per cent. rule was established in Dec., 1907, and a glaze was adopted which a local analyst certified to be within the limit. Samples taken in 1908 yielded 4.7 and 6.6 per cent. of

soluble lead, whereupon the firm substituted a glaze with 1.9 per cent., as certified by the Government Laboratory with satisfactory results. In nine potteries the 5 per cent. limit is in force under Rule 23. There was one case of plumbism in 1908. Two out of 30 glaze samples yielded more than 5 per cent. of lead (but not at the factory where the case occurred), but later samples have been within the limit. There are 20 potteries working under the 5 per cent. limit as regards glaze (Rule 2). In the last three years three cases of plumbism have been reported, but not among the glaze workers. Out of 43 samples examined since 1902, nine exceeded the limit.

Colorimetric test for lead in glazes.—Mr. H. R. Rogers has devised a simple test for lead in the glaze of finished ware. The proportion of lead can be determined approximately so as to distinguish between 2 per cent. and 5 per cent. as follows: A standard solution of hydrofluoric acid is applied to the glaze, and, after 40 seconds' exposure, is absorbed by filter paper, which is then treated with sulphuric acid, washed to remove soluble sulphates, and treated with ammonium sulphide. The black stain on the paper is said to vary in depth of colour with the proportion of lead, and is compared with standard tint obtained in the same way from glazes of known lead contents. Cobalt, iron, manganese, or copper in the glaze do not affect the test.

China and earthenware.—In May a Departmental Committee was appointed to inquire into questions affecting the china and earthenware industry (see this J., 1908, 504).

Industrial diseases.—The Industrial Diseases Committee issued a second report, as the result of which the following were added to the third schedule of the Workmen's Compensation Act, 1906: Glassworkers' cataract (from the glare of molten glass); telegraphists' cramp; eczematous ulceration of the skin produced by dust or liquids; and ulceration of the mucous membrane produced by dust.

Humidity in weaving sheds.—The following conclusions are selected from the Report of the Humidity Committee published in March, 1909:—

1. As regards health and comfort of workers, the wet-bulb, rather than the dry-bulb, temperature is the essential point, and a limit (of wet-bulb reading) should be fixed beyond which no further humidification should be allowed.

2. Schedule IV., 1901, should be amended accordingly, omitting also all dry-bulb temperatures below 50° F., and requiring a minimum difference between the wet and dry-bulb readings.

3. The standard of carbon dioxide for humid sheds is 12 per 10,000 in daylight, and 20 during lighting by gas or oil; and 15 to 23 are suggested for dry sheds, to encourage disuse of humidification. Any excess of carbon dioxide in the open air, beyond the normal 4 parts, is to be taken into account.

5. Cold draughts must not impinge on the workers.

6. The water used for humidification should have a standard of purity.

7. Arrangements should be made for storing clothing.

8. The thermometers should be read by both employers and employed and the results registered, but the records need only be sent to the inspector when irregularities are found.

9. There should be power to prescribe details as to use of hygrometers.

10. Steam pipes should be small and covered with non-conducting material.

11. The floors and walls should be kept clean.

12. All roofs, including those of glass, even on the north side, should be whitewashed from June to September.

13. The present limit of 12 months, within which repetition of an offence renders the occupier liable to a penalty, should be made 24 months.

The expert evidence obtained by the Committee as to the injurious effect of high wet-bulb temperatures is conclusive.

The following data are furnished by Superintending Inspector Bellhouse:—*Method of ventilation:* Exhaust, 392; plenum, 369; both, 177; other, 20. *Method of humidification:* Steam jets alone, 519; Hart's, 134; Matthew and Yates', 39; Parsons', 54; Howarth's, 31;

all and Kay's, 57; Vortex, 29; Drosophore, 5; Pyc's, ; other, 1.

Construction: "Saw-tooth" roof, 896; flat, 2; saw-tooth and flat, 4; louvre, 1; under other rooms, 55.

Cloakrooms: Provided for 100 sheds out of 958.

The large amount of size used causes much dirt, and at this point frequent instructions are necessary.

Annealing of wire by lead.—Four cases of poisoning cured in a works where hot wire was passed through bath of molten lead. The lead oxide formed was carried off by the wire and given off into the air of the rooms it passed over the pulleys. The only method which was all successful was to cover the bath with charcoal, which reduced the lead oxide on the wire as it left the bath.

Aniline poisoning.—Two cases occurred, one in a calico printing works and the other in a dye works. The latter is caused by a quantity of aniline oil being splashed on to a workman's clothing, who, however, continued to work. By inhalation or absorption, or both, he was poisoned and died in a few hours.

Galvanising and ammonium chloride.—In two factories fumes of ammonium chloride given off are drawn off by exhaust fans, condensed in a stream of hydrochloric acid, and the salt recovered. The percentage of recovery so high that it is a commercial success, but, owing to the high initial cost, it is not being generally adopted.

Red lead manufacture.—An entirely new method of manufacture has been established in the Liverpool district, in which all handling of material is superseded by automatic appliances, and all risk of poisoning reduced to a minimum.

Books Received.

THE FUNDAMENTAL PRINCIPLES OF CHEMISTRY. An Introduction to all Text Books of Chemistry. By **WILHELM OSTWALD.** (Translation by H. W. MORSE.) Longmans, Green and Co., 39, Paternoster Row, London; also New York, Bombay, and Calcutta. Price 7s. 6d.

10 volume, containing 341 pages of subject matter, with 65 illustrations, and an alphabetical index. The subject matter receives the following sub-divisions:—
I. Bodies, substances, and properties. II. The three states. III. Mixtures, solutions, and pure substances. IV. Change of state and equilibrium. (The following equilibria are defined:—(i). Liquid-gas; (ii). Solid-liquid; (iii). That between the three states; (iv). Solid-liquid.) V. Solutions. VI. Elements and compounds. VII. Law of combining weights. VIII. Colligative properties. IX. Reaction velocity and equilibrium. X. Isomerism. XI. The ions.

EXERCISES IN PHYSICAL CHEMISTRY. By Dr. W. A. ROTH. Translated by A. T. CAMERON. Archibald Constable and Co., Ltd., 10, Orange Street, Leicester Square, London, W.C. 1909. Price 6s. net.

20 volume, containing 190 pages of subject matter, with 49 illustrations, and an alphabetical index. The subject matter is classified under the following heads:—
I. Introductory. II. Determination of density. III. Determination of molecular weights in solution. IV. Thermo-chemistry. V. Determination of optical constants. VI. The thermostat. VII. Chemical statics and dynamics. VIII. Electrochemistry. IX. Foundations. X. Electrical conductivity. XI. Faraday's law. Transport numbers. XII. Measurement of differences of potential. XIII. Electrostatics. Appendix.

SUGAR AND ITS MANUFACTURE. By H. C. PRINSEN GEERLIGS, Late Director of the West Java Sugar Experiment Station. Norman Rodger, Altrincham, Manchester. 1909. Price 12s. net.

LARGE 8vo volume, containing 350 pages of subject matter, and the alphabetical index. The subject in this work is divided into two parts: Part I., devoted to "THE RAW MATERIAL," and Part II., to "THE SUGAR MANUFACTURE." Under Part I., the subject is sub-

divided as follows:—(i). The constituents of cane sugar (ii). The proportion and distribution of the constituents of sugar cane. PART II.: (i). Extraction of the juice. (ii). Clarification. (a). Defecation. (b). Carbonatation. (iii). Lime and lime cream. (iv). Other clarifying and decolorising agents. (v). Filtration. (vi). Concentration of the juice. (vii). Curing. (viii). Exhausted molasses.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journal in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 14,024. Michaelis. Centrifugal separators.* June 15.
14,115. Keller. Conveying and compressing gases [Ger. Appl., March 6, 1909.]* June 16.
14,119. Mills (Arabul Manuf. Co.). See under XII.
14,514. Steger. Apparatus for separating particles of liquid gases and vapours.* June 21.

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,632 (1908). Köhnke. Evaporator for sea-water. June 23.
14,155 (1908). Read and Campbell. Filters. June 23.
18,831 (1908). Peyton. Packing pieces for chemica absorption, condensing, and like towers. June 30.
25,643 (1908). Tiemann. Drying non-pulverulent materials. June 23.
2218 (1909). Read and Campbell. Capsules for holding compressed or liquefied gas. June 30.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 14,200. Hall. Process for purifying gas. [U.S. Appl. July 11, 1908.]* June 17.
14,508. Ewing. Gas retorts. June 21.
14,655. Wolfram Lampen A.-G. and Goll. Carbonising metallic glow-lamp filaments made with organic binding agents. [Ger. Appl., Feb. 15, 1909.]* June 22.
14,938. Jung. Manufacture of incandescent mantles for gas lighting. June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

- 14,031 (1908). Johnson. Retort gas-making apparatus. June 23.
16,027 (1908). Rincker and Wolter. Production of gas from tar, oil, etc., in gas-producer plant. June 23.
19,363 (1908). Pettibone. Manufacture of producer gas or water gas. June 23.
1247 (1909). Zailer. Pent products for fuel purposes. June 23.
5163 (1909). Severin. Manufacture of incandescent mantles. June 30.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATION.

- 14,139. Hutchinson. Coal tar compounds. June 16.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

13,903. Aniline Colour and Extract Works. Manufacture of *p*-amino-*n*-oxvazo colouring matters. [Ger. Appl., March 29, 1909.]* June 14.

13,904. Aniline Colour and Extract Works. Manufacture of *o*-oxydisazo colouring matters. [Ger. Appl., March 29, 1909.]* June 14.

13,907. Johnson (Badische Anilin und Soda Fabrik). Manufacture of anthracene colouring matters. June 14.

14,143. Ransford (Cassella and Co.). Manufacture of sulphide colours from carbazol derivatives. June 16.

14,311 and 14,312. Newton (Bayer und Co.). Manufacture of new dyestuffs. June 18.

14,314. Inray (Soc. Chem. Ind. in Basle). Manufacture of brown vat dyestuffs of the indigo series. June 18.

14,315. Inray (Soc. Chem. Ind. in Basle). Manufacture of substantive tetrazo dyestuffs.* June 18.

14,316. Bloxam (Chem. Fabr. Griesheim-Elektron). Manufacture of mono-azo dyestuffs suitable for use as lakes. June 18.

14,820. Newton (Bayer und Co.). Manufacture of acid wool dyestuffs. June 24.

14,940. Wetter (Chem. Fabr. Grünau, Landshoff, und Meyer). Manufacture of alizarin preparations suitable for dyeing and printing.* June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

19,641 (1908). Newton (Bayer und Co.). Manufacture of alizarin. June 23.

24,604 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of colouring matters of the anthracene series. June 30.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

14,092. Bleachers Assoc., Ltd., and Rusden. Treating woven piece goods. June 16.

14,112. Friedrich. Producing durable solutions for pinning, etc.* June 16.

14,477. Hart. Rendering fabrics waterproof and gas-tight, and waterproofing yarns, cords, &c. June 21.

14,760. Farjas and Jaboin. Radium-treated fibres. Fr. Appl., Dec. 4, 1908.]* June 23.

14,940. Wetter (Chem. Fabr. Grünau, Landshoff, und Meyer). *See under IV.*

14,959. Farjas and Jaboin. Fibres treated with radium. Fr. Appl., Feb. 16, 1909.]* June 26.

COMPLETE SPECIFICATION ACCEPTED.

13,226 (1908). Hanson. Dyeing machines and the like. June 23.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

14,300. Teisset and Prat. Impts. in Kessler's apparatus or concentrating sulphuric acid. [Fr. Appl., Dec. 31, 1908.]* June 18.

14,313. Newton (Bayer und Co.). Manufacture of a double compound of zinc hydrosulphite and sodium sulphite. June 18.

14,469. Rollason. Obtaining nitrates from atmospheric air. June 21.

14,725. Nanton, de Marsac, and Tesse. Alkaline solvents and the manufacture thereof.* June 23.

14,744. Evans and Macan. *See under X.*

COMPLETE SPECIFICATIONS ACCEPTED.

12,980 (1908). Eberhard. Increasing the mobility and activity of water-glass. June 23.

25,535 (1908). Blagburn. Obtaining nitrogen from the air. June 23.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATION.

14,761. Farjas. Permanently radio-active glass. [Fr. Appl., April 2, 1909.]* June 23.

COMPLETE SPECIFICATIONS ACCEPTED.

27,806 (1907). Roman Brick Co., and Schauer mann. *See under IX.*

7823 (1909). Sievert. Manufacture of glass plates. June 23.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

14,192. Govan. Making concrete. June 17.

14,281. Glover. Plant for crosscutting timber. June 18.

COMPLETE SPECIFICATIONS ACCEPTED.

27,806 (1907). Roman Brick Co., and Schauer mann. Manufacture of bricks, blocks, and pottery used in building. June 23.

22,126 (1908). Reich. Production of clay tiles resembling natural sandstone. June 30.

23,782 (1908). Isenschmid. Composition for making imitation marble. June 23.

X.—METALS AND METALLURGY.

APPLICATIONS.

13,869. Tucker. Treatment of iron and steel for prevention of rust. June 14.

14,129. Carson. Apparatus for treating ores or other materials containing volatile metals. June 16.

14,245. Angley. Open-hearth process for producing malleable and steel castings. June 17.

14,342. Frank. Treatment of zinc.* June 18.

14,351. Harrison (Resinelli). Furnaces for producing cast iron and steel.* June 18.

14,357. Hinchley. Plant for treating sheets by the process of sherardizing. June 19.

14,372. Parnell. Treatment of ores. June 19.

14,541. Hübner. Desulphurising ores.* June 21.

14,744. Evans and Macan. Treatment of calcined ores containing zinc or zinc and lead to produce zinc white or zinc sulphate. June 23.

14,812 and 14,813. Smallwood. Furnaces for roasting, calcining, and smelting ores, heating metals, &c. June 24.

14,945. Namaqua Copper Co., and James. Separation of metals from ores by flotation. June 26.

14,946. Soc. Electro-Métallurgique Française. Manufacture of pure nickel. [Fr. Appl., June 27, 1908.]* June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

6148 (1908). Lockwood and Samuel. Treatment of ores. June 30.

12,534 (1908). Miller. Crucible furnaces for melting steel and other metals. June 23.

13,513 (1908). Armstrong. Furnaces for obtaining zinc and lead. June 30.

20,902 (1908). Williams. Extraction of metals from ores by solar heat. June 23.

23,497 (1908). Sulman. Separation of zinc from its ores or compounds. June 30.

24,503 (1908). Rogerson and Donaldson. Treatment of ores. June 30.

25,620 (1908). Tonceda. Alloys for bearing metals. June 23.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

14,288. Schott and Zeiss Stiftung. Electrolytic apparatus having a liquid anode. [Ger. Appl., June 26, 1908.]* June 18.

14,660. Thum. Electrolytic apparatus.* June 22.
 14,858. Bingham. Electric furnace electrodes. June 26.
 14,937. Grunwald. Electric induction furnaces. [Addition to No. 3599 of 1909. Ger. Appl., Oct. 2, 1908.]* June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

1345 (1909). British Thomson-Houston Co. (General Electric Co.). Aluminium electrolytic cells. June 30.
 3599 (1909). Grunwald. Electric induction furnaces. June 23.
 7396 (1909). Grunwald. Electric induction furnaces. June 23.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATIONS.

14,119. Mills (Arabol Manufacturing Co.). Emulsifier, emulsifying process, and emulsion.* June 16.
 14,750. Lever Bros., Ltd., and Edwards. Extraction of crude glycerin from the salt produced during concentration of soap or other lye. June 23.
 14,875. Fletcher, Mays, and Mays. Rapid tallow-melting process. June 26.

COMPLETE SPECIFICATION ACCEPTED.

14,623 (1908). Moore-Irvine. Apparatus for making soap, &c. June 23.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A).—PIGMENTS, PAINTS.

APPLICATIONS.

14,744. Evans and Macan. *See under X.*
 14,835. Erbslow and Coudron. Manufacture of white lead.* June 24.

(C).—INDIA-RUBBER.

APPLICATION.

13,984. Robinson. Rubber substitute. June 15.

XIV.—TANNING, LEATHER, GLUE, SIZE, &c.

APPLICATION.

14,516. Redlich and Pollak. Treatment of quebracho extracts. June 21.

COMPLETE SPECIFICATIONS ACCEPTED.

13,768 (1908). Landenberger (Marwedel). Process of tanning. June 30.
 4130 (1909). Lake (Fiber Products Co.). Production of artificial leather. June 23.

XVII.—BREWING, WINES, SPIRITS, &c.

APPLICATION.

14,266. Elmassian. Dry extraction of barley malt. June 17.

COMPLETE SPECIFICATION ACCEPTED.

16,987 (1908). Carroll. Distilling and treating spirits. June 30.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A).—FOODS.

APPLICATIONS.

14,491. Remfry. Manufacture of self-raising flour. June 21.
 14,931. Tildesley, Ritchie, and Watkins. Process for improving flour. June 26.

(B).—SANITATION; WATER PURIFICATION.
APPLICATION.

14,874. Coplans. Rapid preparation of potable water. June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

13,632 (1908). Köhuke. *See under I.*
 6013 (1909). Felten und Guillaume Lahmeyerwerke. Apparatus for sterilising water with ozone. June 30.

XIX.—PAPER, PASTEBOARD, &c.

APPLICATIONS.

14,016. Wells, and British Xylonite Co., Ltd. Preparation of xylonite or celluloid. June 15.
 14,779. Stone. Production of a new paper product. June 24.

COMPLETE SPECIFICATION ACCEPTED.

6277 (1909). Turner and Maxwell. Treatment of bamboo pulp and similar materials. June 30.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

13,902. Skita. Manufacture of camphene. June 14.
 13,912. Zimmermann (Chem. Fabr. auf Actien vorm. E. Schering). Manufacture of cerium phenol compounds.* June 14.
 14,663. Wellcome and Pyman. Manufacture of therapeutic compounds. [Addition to No. 314 of 1909.] June 22.
 14,762. Farjas. Radioactive products possessing permanent activity. [Fr. Appl., Apr. 14, 1909.]* June 23.
 14,805. Wetter (Rütgerswerke). Meta-cresol-ortho-oxalic ester.* June 24.
 14,918. Wellcome and Pyman. Manufacture of therapeutic compounds. June 26.
 14,960. Farjas. Permanently radio-active products. [Fr. Appl., May 8, 1909.]* June 26.

COMPLETE SPECIFICATIONS ACCEPTED.

15,573 (1908). Newton (Bayer und Co.). Manufacture of purine derivatives. June 30.
 20,377 (1908). Imray (Meister, Lucius, and Brüning). Manufacture of 1-aryl-2,4-dialkyl-halogenmethylpyrazolones. June 23.
 22,085 (1908). Newton (Bayer und Co.). Manufacture of alkyl esters of methylsuccinic acid. June 30.
 27,096 (1908). Knoll und Co. Manufacture of condensation mixtures from phenols and aldehydes. June 30.
 28,011 (1908). Riechert. Production of hydrogen iodide and hydrogen bromide addition compounds of lecithin. June 30.
 2020 (1909). Fritzsche und Co. Manufacture of the *n*-propyl ester of *p*-nitro- and *p*-amino-benzoic acid. June 23.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

APPLICATIONS.

14,406. James (Cie. Gén. des Phonographes, Cinématographes, et Appar. de Précision). Process for obtaining photographs in colours.* June 19.
 14,502. Kogel. Preparation of photographic prints.* June 21.
 14,824. James (Cie. Gén. des Phonographes, Cinématographes, et Appar. de Précision). Colouring photographic prints by previously toning.* June 24.

XXII.—EXPLOSIVES, MATCHES, &c.

COMPLETE SPECIFICATION ACCEPTED.

15,916 (1908). Kilburn (Pieper). Explosives. June 23

Journal of the Society of Chemical Industry.

No. 14, Vol. XXVIII.

JULY 31, 1909.

No. 14, Vol. XXVIII.

The Society of Chemical Industry.

Past Presidents.

Sir Henry E. Roscoe, B.A., D.C.L., LL.D., Ph.D., F.R.S.	1881—1882.
†Sir Frederick A. Abel, Bart., K.C.B., G.C.V.O., D.C.L., D.Sc., F.R.S.	1882—1883.
†Walter Weldon, F.R.S.	1883—1884.
†Sir Wm. H. Perkin, LL.D., Ph.D., F.R.S.	1884—1885.
E. K. Muspratt, LL.D.	1885—1886.
David Howard	1886—1887.
Sir James Dewar, M.A., LL.D., F.R.S.	1887—1888.
Ludwig Mond, Ph.D., F.R.S.	1888—1889.
†Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
†E. Rider Cook	1890—1891.
J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
†Sir John Evans, K.C.B., D.C.L., LL.D., Sc.D., F.R.S.	1892—1893.
†E. C. C. Stanford	1893—1894.
Sir Edward Thorpe, C.B., LL.D., Sc.D., Ph.D., F.R.S.	1894—1895.
Thomas Tyrer	1895—1896.
†Edward Schuuck, Ph.D., F.R.S.	1896—1897.
Frank Clowes, D.Sc.	1897—1898.
George Beddy, LL.D., F.R.S.	1898—1899.
C. F. Chandler, D.Sc., M.D., Ph.D., LL.D.	1899—1900.
Sir Jos. W. Swan, D.Sc., M.A., F.R.S.	1900—1901.
Ivan Levinstein	1901—1902.
Sir Wm. Ramsay, K.C.B., D.Sc., LL.D., F.R.S.	1902—1903.
Wm. H. Nichols, M.S., LL.D., D.Sc.	1903—1904.
Edward Divers, M.D., D.Sc., F.R.S.	1904—1905.
Enstace Carey	1905—1906.
Sir Boverton Redwood, D.Sc.	1906—1907.
Raphael Meldola, F.R.S.	1907—1908.
	1908—1909.

† Deceased.

LIST OF COUNCIL, 1909—1910.

President: President Ira Remsen.

Vice-Presidents:

G. Beilby, F.R.S.	Dr. R. Messel.
Enstace Carey.	Sir Boverton Redwood.
J. T. Dunn.	Walter F. Reid.
Grant Hooper.	Geo. C. Stone.
R. Ling.	Dr. T. B. Wagner.
of R. Meldola, F.R.S.	Dr. C. Woodcock.

Ordinary Members of Council:

of P. Phillips Bedson.	D. Lloyd Howard.
of W. Hodgson Ellis.	Dr. Charles A. Keane.
near Guttman.	Prof. W. R. Lang.
Hemingway.	Harold Van der Linde.
of G. G. Henderson.	B. E. R. Newlands.
of W. R. E. Hodgkinson.	Dr. Julius Raschen.

Sectional Chairmen and Secretaries:

T. Slater Price.	BIRMINGHAM.	F. R. O'Shaughnessy.
Milton L. Hersey.	CANADIAN.	Alfred Burton.
ax Muspratt.	LIVERPOOL.	W. Roscoe Hardwick.
J. Lewkowitsch.	LONDON.	Julian L. Baker.
H. Clayton.	MANCHESTER.	Julius Hübnar.
J. Potter.	NEWCASTLE.	Dr. F. C. Garrett.
W. H. Walker.	NEW ENGLAND.	Alan A. Claffin.
aximilian Toch.	NEW YORK.	Dr. H. Schweitzer.
J. Pentecost.	NOTTINGHAM.	S. R. Trotman.
J. Playfair.	SCOTTISH.	Dr. G. B. Neave.
rof. J. A. Schofield.	SYDNEY, N.S.W.	T. U. Walton.
rof. W. M. Gardner.	YORKSHIRE.	Thomas Fairley.

Honorary Treasurer:

Thomas Tyrer, Stirling Chemical Works, Stratford, E.

Honorary Foreign Secretary:

Dr. Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell, 59, Palace Chambers, Westminster, S.W.

Telegraphic Address: 59, Palatable, London.

Telephone Number: 715, Victoria.

THE JOURNAL.

Publication Committee.

The President.

Julian L. Baker.	J. Lewkowitsch, Ph.D.
J. Carter Bell.	A. R. Ling.
C. F. Cross.	W. Maenab.
Edw. Divers, M.D., D.Sc., F.R.S.	N. H. Martia.
T. Fairley.	B. E. R. Newlands.
Prof. A. G. Green.	John Pattinson.
H. Hemingway.	A. G. Perkin, F.R.S.
John Heron.	F. B. Power, Ph.D.
Prof. W. R. E. Hodgkinson,	Prof. H. R. Procter.
Ph.D.	Sir Boverton Redwood.
G. T. Holloway.	Walter F. Reid.
E. Grant Hooper.	John Spiller.
David Howard.	L. T. Thorne, Ph.D.
Julius Hübnar.	Thomas Tyrer.
Charles A. Keane, D.Sc., Ph.D.	

Editor:

Watson Smith, 34, Upper Park Road, Haverstock Hill, N.W.

Assisted by the following Staff of Abstractors.

J. Allan XII.	A. T. Larter, B.Sc. II, IV.
E. F. Armstrong, (XVI, XVII,		R. Lessing, Ph.D. III, VII.
Ph.D., D.Sc. (XVIII, XX,		A. G. Levy, B.Sc. VIII, IX.
H. G. Bennett XIV.	E. W. Lewis XIII.
J. O. Braithwaite XX.	G. W. Macdonald, M.Sc. XXII.
J. F. Briggs XVI, XVII,	F. Marsden, Ph.D. IV, V.
R. B. Brown XIX, XX.	C. A. Mitchell, XII, XXII.
H. Brumwell IV, V.	B.A.	
T. F. Burton, (III, XX, XXI,		R. S. Morrell, Ph.D. XIII.
B.Sc. Patent List.	Barker North V, XI.
J. C. Cain, D.Sc. IV, V, XX.	T. H. Pope, XVI, XVII,
W. A. Caspari, Ph.D. XI.	B.Sc. XX, XXI.
W. H. Coleman I, III, VII.	O. Reinherz VII, IX, XVIII.
P. F. Crosland V, VI.	F. Rowley X, XI.
J. T. Dunn, D.Sc. VII, X.	Chas. Salter II, III, IX,
L. Eynon, B.Sc. XVI, XVII.	F. Shedden XX.
E. Feilmann, Ph.D. IV, V.	A. Shonk III, VII, X, XI.
J. Wilberforce Green XVIII,	R. L. Siau XVI, XVII.
C. J. Guttman, B.Sc. XXI.	W. P. Skerchely XII,
Walter C. Haas II, VIII,	F. Southerden, B.Sc. IX, XX.
cock, B.A. IX.	H. H. Stephenson VIII, IX.
S. H. Higgins, M.Sc. V.	A. B. Steven, B.Sc. IV, V.
J. W. Hinchley VII, X, XI.	L. J. de Whalley, B.Sc. XVI.
O. F. Hudson X.	C. A. Wigham, B.Sc. X.
J. H. Johnston XVIIIB.		

Birmingham Section.

Chairman: T. Slater Price.

Committee:

F. H. Alecock.	O. F. Hudson.	R. S. Morrell.
N. Parr Booth.	E. Hunt.	H. T. Pinnock.
P. F. Frankland.	J. F. Liverseege.	E. C. Rossiter.
H. L. Heathcote.	C. A. Mander.	Harry Silvester.
A. H. Hioras.	J. C. Mann.	

Hon. Local Secretary and Treasurer.

F. R. O'Shaughnessy, Tyburn, nr. Birmingham.

Canadian Section.

Chairman: Milton L. Hersey.

Vice-Chairmen:

Wallace P. Coboe, A. McGill, W. Lash Miller

Committee:

M. L. Allard.	Nevil N. Evans.	W. B. Tindall.
E. G. R. Ardagh.	C. F. Heebner.	T. H. Wardleworth.
C. F. Bardorf.	F. L. Langmuir.	G. J. Webster.
W. Hodgson Ellis.	A. Nighorn.	

Hon. Treasurer: J. W. Bain, 90, Charles Street, Toronto.

Hon. Local Secretary:

Alfred Burton, 44, York Street, Toronto.

Liverpool Section.

Chairman: Max Muspratt.

Vice-Chairman: J. T. Conroy.

Committee:

J. Campbell Brown.	W. Ramsay.	J. W. Towers.
Arthur Carey.	W. H. Roberts.	Alex. Watt.
Eustace Carey.	H. B. Stocks.	W. Collingwood
G. C. Clayton.	J. M. Taylor.	Williams.

Hon. Treasurer: W. P. Thompson.

Hon. Local Secretary:

W. R. Hardwick, 13, Batavia Buildings, Hackins Hey, Liverpool.

New York Section.

Chairman: Maximilian Toch.

Committee:

L. N. Adler.	W. D. Horne.	R. W. Moore.
T. Lynton Briggs.	L. S. Kohnstamm.	T. J. Parker.
V. Coblenz.	Hugo Lisber.	F. J. Pond.
W. F. Fuerst.	E. G. Love.	Geo. C. Stone.
Bernhard C. Hesse.	C. F. McKenna.	

Hon. Treasurer: Frank C. R. Hemingway, 133, Front Street, New York City, U.S.A.

Hon. Local Secretary:

H. Schweitzer, 117, Hudson Street, New York City, U.S.A.

London Section.

Chairman: J. Lewkowitsch.

Vice-Chairman: E. Grant Hooper.

Committee:

A. C. Chapman.	G. T. Holloway.	F. B. Power.
W. P. Dreyer.	D. L. Howard.	W. F. Reid.
A. Harden.	C. A. Keane.	L. T. Thorne.
H. Hemingway.	W. J. Leonard.	J. A. Voelker.
W. R. Hodgkinson.		

Hon. Local Secretary and Treasurer:

Julian L. Baker, Stainesbury Holt, Kingston Road, Staines.

Nottingham Section.

Chairman: S. J. Pentecost.

Vice-Chairman: O. Quibell.

Committee:

L. Archbutt.	J. F. Kempson.	H. J. S. Sand.
F. J. R. Carulla.	F. Stanley Kipping.	G. J. Ward.
J. Golding.	T. H. Lloyd.	J. White.
T. F. Harvey.	J. M. C. Paton.	J. T. Wood.

Hon. Local Secretary and Treasurer:

S. R. Trotman, 1, Regent Street, Nottingham.

Manchester Section.

Chairman: R. H. Clayton.

Vice-Chairman: G. J. Fowler.

Committee:

MR. HARRY SILVESTER IN THE CHAIR.

THE SPONTANEOUS HEATING OF COAL. PARTICULARLY DURING SHIPMENT.

BY RICHARD THRELFALL, F.R.S.

The literature of the subject of Spontaneous Heating of Coal is voluminous, and I do not expect to be able to do more than bring together some of the results obtained by the chief investigators of the matter. An index to the literature appears as an appendix to the Report of the N.S.W. Royal Commission, 1896, but what I shall have to say has already been more or less published in the reports of two Royal Commissions which sat at Sydney, N.S.W., from 1896 to 1900, with both of which I was connected, and in a Board of Trade (Marine Department) Paper No. 110 in the matter of the damage by fire sustained by the ship "Walter H. Wilson," the technical part of which paper was written by me. In these contributions a great many administrative matters are discussed, and a good deal of very human evidence is considered—so that the scientific side of the questions involved is not the most prominent. The problem of spontaneous heating is, however, in its general form merely a question of physics and chemistry, and it is possible to condense the treatment somewhat by regarding the matter purely from this standpoint.

Observations which have been made on the large scale of the firing of mines, of heaps of coal, and of coal-laden ships will then form an interesting commentary on the deductions which may be arrived at on purely scientific grounds. Coal may be considered from many points of view, but the most instructive way of looking at it for our present purpose is from the point of view of its origin in plant constituents. It thus appears substantially as a condensation product of bodies of the cellulose class mixed with impure clay and sand—and with secondary products such as pyrites or more usually marcasite. It is instructive to recall the fact that decacylene or trinaphthalenebenzene, $C_{36}H_{18}$, described by Rehlander (Ber., 1903, 36, 1553) Dziewonsky (Ber., 1903, 36, 962) contains only 4 per cent. of hydrogen, which is not more than is commonly present in coke and coal. It is tempting, therefore, to regard all cokes in the way suggested by Dziewonsky, viz.: as very advanced condensation compounds, and Dziewonsky's suggestion might probably be extended with some modification to coals themselves.

There is an almost or quite unbroken series of bodies starting from wood—passing through peat and lignite to gas coals, and finally to anthracite, with progressive condensation. The degree to which this condensation has been carried can be roughly tested by distillation up to a red heat, the carbon so removed being commonly referred to as "volatile carbon" in contradistinction to the so-called "fixed carbon" remaining in the coke. The further the process of coal formation has proceeded the larger is the proportion (roughly speaking) of "fixed carbon." I need hardly say that both these terms, though having a fairly well defined analytical meaning, only indicate in a rough way the degree to which condensation has attained. However it has been pointed out by Trémy and by Fayol (Bulletin de la Société de l'Industrie Minérale, 8 (1879)).—and is indeed common knowledge, that the stability of coal in presence of oxidising reagents (i.e., nitric acid and hypochlorites) increases as we pass from lignites towards anthracite. Fayol classifies coals in order of inflammability, and naturally places lignite at one end of the series and anthracite at the other, both from tests by direct ignition of samples by flame and also by noting the temperature at which the coal in powder ignited in a stream of air.

One of the most important investigations which have been made in the laboratory on the oxidation of coal by air, is due to Dr. E. Richters—chemist in the Mining School of Waldenburg, whose first paper was published in "Dingler's Polytechnisches Journal," 190, Dec., 1868, and continued in Vols. 193 and 195. Translations of these papers are published in extenso in The Report of the N.S.W. Commission on Coal Cargoes No. 1, 1897. Richters was not the earliest investigator—important experiments having been previously made by "Fleck, Stein, Grundmann, Varrentrapp, Sauerwein and others," to quote the beginning of his first paper.

The investigation which forms the subject-matter of the paper consists in heating powdered coal, of the coking variety, from a mine at Waldenburg, for some hours in a slow stream of dry air free from carbon dioxide. The temperature employed was about 200° C. The following is a typical analysis showing the effect of this treatment when the heating was continued for 10 hours at 190° C., and the coal increased in weight by 4.21 per cent.:

	Coal dried in the desiccator. Weight 2 grms.	Heated coal.	104.21 parts by weight of the heated coal, contained, consequently:
	per cent.	per cent.	parts.
Carbon	86.82	82.19	85.65
Hydrogen	4.26	3.38	3.52
Oxygen and nitrogen	6.40	11.96	12.47
Ash	2.52	2.47	2.57
			104.21

One hundred grms. of coal accordingly lost by heating 0.74 grm. of hydrogen and 1.17 grms. of carbon. On the other hand, it gained 6.07 grms. of oxygen. The water which made its appearance in the calcium chloride tube weighed 0.118 grms., corresponding to .66 per cent. of hydrogen. The increase in weight of the soda lime tube was 0.092 grms., corresponding to 1.25 per cent. of carbon. The result of this experiment is to show that by heating the coal in air there is complete oxidation of the hydrogen and carbon which it loses.

From this and six similar experiments Richters remarks, "If we heat at a temperature of from 180° to 200° C. coal in powder, which has been previously dried in a desiccator until its weight becomes constant, an increase in weight soon becomes apparent. For instance, according to the experiments which I have hitherto made, after heating for 12 hours the weight may increase by several per cent.; in 20 hours the increase of weight has reached its maximum, and any further heating then produces a diminution in weight. Coal which has gained in weight resembles unheated coal in little more than in appearance. The differences between heated and unheated coal are:—(1) The heated coal has a greater specific gravity than the unheated; (2) the chemical constitution is different; (3) when heated to a red heat, it behaves differently from ordinary coal; (4) coal, which has been heated, abstracts moisture from the atmosphere much more freely than the normal variety."

Richters' second paper (Dingler, 193, p. 51, July, 1869) contains an account of the absorption of oxygen by coal at temperatures between 15° and 21° C., each experiment lasting a week to ten days. The result is summed up by Richters in the words: "So much, however, follows from my observations with full certainty, namely, that perfectly dry coal, as well as air-dried coal, is able to absorb oxygen without exhaling carbon dioxide, both from dry air and from air saturated with water vapour. I shall show in another communication that in this behaviour of coal we have the key to the explanation of a whole series of phenomena, which without this key can hardly be explained. I must not omit to draw attention, however, to an objection which may be raised against the above conclusion, namely, that the oxygen is absorbed not by the coal itself, but by the pyrites which is present with it. If we calculate the total ash content in sulphur of the coal as if it were ferric sulphide, we find that the coal from the Carl seam contains .31 per cent., from the Robert seam

0.42 per cent., and from the Jacob seam .36 per cent. of pyrites. These coals, therefore, are extraordinarily poor in pyrites. Moreover, pyrites is quite unaltered in dry air. In moist air, however, it does absorb a certain quantity of oxygen, but in very small proportions, so that if we mix an indifferent substance—for instance, quartz sand—with the pyrites, so as to make a mixture having the same pyrites content as the above-mentioned coals, it appeared that, in the first case, no oxygen was absorbed and in the second only a very small quantity, even when the mixture was left for a very long time with a measured volume of air."

This memoir then deals with the action of oxidising agents upon coal and charcoal, with the result that charcoal is found to react very similarly to coal.

In the next paper (Dingler, 1870, 195, 315) Richters sums up the results of his investigations of the subject. His note on the absorption of oxygen and carbonic acid may be given verbatim, as its importance cannot be overstated: "Coal absorbs carbon dioxide with the greatest readiness. The volume of this gas, which is taken up in a given time, is often greater than three times the volume of oxygen which could be taken up. Samples of coal whose absorptive power for oxygen has almost vanished, so much so that 20 grms. will only take up about 1 cub. centimetre of oxygen, will absorb in a few hours at least their own volume of carbon dioxide. If a sample of coal saturated with carbon dioxide is brought into contact in a closed space with atmospheric air, we find at first an increment of volume as if the carbon dioxide was given off. Soon, however, the volume again begins to diminish. If, at the same time, a small bulb containing caustic potash is introduced in the absorption tube, or if the sides of the latter are moistened with a solution of caustic potash, the absorption of oxygen goes on very quickly, as does the separation of the carbon dioxide, which of course forms a compound with the caustic potash. If we leave samples of coal saturated with carbon dioxide for 36 hours under the receiver of an air pump exhausted to 2 ins. of mercury, the greater portion, but not all, of the absorbed carbon dioxide is given off. If a sample of coal which has been so treated is then saturated with moisture and again put into an absorption tube, it begins to take up oxygen with the same avidity as when it was freshly prepared, and this whether any potash is present or not. If potash is present, however, we soon discover that a certain quantity of carbon dioxide has been liberated, which shows that the absorption of oxygen is at first accompanied by a separation of carbon dioxide, and that this carbon dioxide will again be taken up by the coal in the absence of any other substance capable of absorbing it.

"If coal which has been saturated with carbon dioxide is boiled for half an hour in water and is then air-dried, so that it remains saturated with hygroscopic moisture, it is found to have recovered its original absorptive properties.

"Coal which has been exposed for a long time to the air, until it has lost its power of absorbing oxygen, behaves in a completely different manner when the foregoing experiments are performed upon it. For instance, when exposed under the receiver of an air-pump it does not by any means recover its original power of absorption, though this power is still partly restored by boiling out with water. Carbon dioxide is either not absorbed at all by such coal, or in only very small proportions."

The question as to the effect of keeping coal for a considerable time at a temperature of 70°–80° C. is then approached by heating samples of dried coal for 14 days at the temperature in question. The change occurring is exhibited by six analyses, of which the following are typical:—

	Before heating.	After heating.
	per cent.	per cent.
Carbon	81.99	81.07
Hydrogen	4.92	4.71
Oxygen and nitrogen	10.19	11.32
Ash	2.90	2.90
	100.00	100.00

It is not stated which of the numbers is estimated by difference.

The calorific value of the coal was reduced from 8084 to 7842 (calories per (German) pound). The coking power (scale not defined) was reduced from 2 to 1.6.

In regard to the weathering of coal as affected by moisture, reference is made to some experiments by Thompson, the results of which are not confirmed by Richters, but the effect of moisture on the weathering on the large scale is not investigated. The following remark is, however, of importance: "If we take two tubes, and into one of them introduce air-dried, and into the other moist coal, both being freshly won, the first absorbs oxygen much more rapidly than the second. If, in addition, small bulbs containing fused chloride of calcium are introduced alongside the dry sample of coal so that the coal gets gradually drier, the intensity of the absorption of oxygen becomes greater. The same is the case if the coal has been dried for a day over sulphuric acid, although during this process a very considerable quantity of oxygen must certainly have been taken up." This experiment is more decisive against the theory that the oxidation observed was due to pyrites and not to coal, than the one previously mentioned, as pyrites requires water for its oxidation. Richters does not appear to have tested the point by analysing the oxidised coal for sulphuric acid or sulphates.

The influence of pyrites on the absorption of oxygen at ordinary temperatures was next tested by Richters, both when the samples were wet and when they were dry—with the result that the coal containing 3.04 per cent. sulphur absorbed oxygen rather more quickly wet than dry—the reverse of the effect with coal containing less sulphur; the difference was, however, very small.

In Dingler's Polyt. J., 195, 449, Richters applies his results to a discussion of the spontaneous heating of coal. As the ground was traversed a little later by Fayol, who experimented on a much larger scale, we need not do more than note the main features of the paper. It was concluded that pyrites can have little or no effect on the spontaneous heating of the coal examined, because the 1.01 per cent. of pyrites could only heat the coal to 72° C. if no heat escaped, and if the heat of oxidation was equal to the sum of the heats of oxidation of the iron and sulphur regarded as free. On the other hand, the heat due to the oxidation of the coal by the oxygen absorbed in 12 days was shown to be much greater. This is, of course, clear from the figures given for the calorific power before and after heating to 70°–80° C., the effect of the higher temperature being merely to accelerate the rate of absorption of oxygen. The heat evolved during 12 days' oxidation at 70°–80° C. was calculated by Richters to be sufficient to raise the temperature of the coal to 1100° C.

The second classic on the subject of the spontaneous combustion of coal is entitled "Études sur l'altération et la combustion spontanée de la houille exposée à l'air," by Henri Fayol, Ingénieur, Directeur des Houillères de Commentry et de Montvicq. This was published originally in the "Bulletin de la Société de l'Industrie Minérale, Second Series, Vol. 8, 3rd part, 1879 (Dunod, Quai des Augustins 49, Paris). The separate copy of this paper kindly sent to me by M. Fayol in 1899 forms a volume of 260 pages, and is certainly the finest example of a published technical investigation I have ever seen or heard of. It should be read by every student in order that he may learn how worthy a subject technical research can be if approached in a critical and scientific spirit. The colliery of Commentry is situated in the North of France, near the Belgian frontier, and produces a bituminous coal burning with a long flame, much used for gas-making. The fracture is rhombohedral—the ash varies from 0.5 to 15 per cent., with an average of about 7 per cent.—even small samples contain very variable amounts of ash in different parts. The other impurities are clay, gypsum—pyrites spread through the mass in flakes—rarely in crystals. The average pyrites content is 1 per cent., but special samples may contain up to 5 per cent. The slack before washing contains 13 per cent. of ash, reduced by washing to 7 per cent.—and when coked in a Belgian oven gives 22 per cent. to 63 per cent. of hard bright coke, which is used in blast

urnaces. The installation of the coke ovens enabled Fayol to keep large quantities of coal at various specified temperatures for long periods of time. In addition to the coal of Commentry, 24 other kinds of coal were more or less investigated, ranging from anthracite to lignite, and from lignite to boghead coal from Scotland.

The first series of researches may be regarded as an extension of Richters' experiments, but the quantities of coal employed—necessitated by the condition of having enough to start with to give perhaps 50 samples, amounted to several kilogrammes. The phenomena investigated as functions of time, at each temperature, and in the presence of air were:—1. Weight. 2. Yield of coke. 3. Coking power, referred to an arbitrary scale in which 0 denotes a coal cohering to a hard solid ingot. 4. Yield of gas on subsequent distillation under fixed conditions, per 100 grms. of the exposed coal. 5. Illuminating power of gas produced.

FIG. 1.

Commentry coal in powder. Variation of weight.
Time of exposure to the air in days.

FIG. 2.

Commentry coal in powder. Variation of weight.
Time of exposure to the air in hours.

The general result as shown by the curves is that the weight increases or decreases at first according to the temperature, but after a long period, when the temperature is over 100° C., the weight tends to fall.

The yield of coke (which rises slightly at first) and the coking power tend to fall off after long periods of exposure; the yield of gas per 100 grms. of the material is not much affected after long periods, but the illuminating power falls off rapidly. There are considerable differences according to the kind of coal employed, but it is impossible to give an adequate idea of this investigation by a short abstract, as it comprised 23 kinds of fuel, each in at least two sizes, and the observations extended over three hundred days, the observations at first being at intervals of a few hours at most. The results are set out on 175 sets of curves showing the behaviour of the samples for each of the five properties enumerated and at six temperatures, viz., 25°, 50°, 75°, 100°, 150°, and 200°, and, while the

FIG. 3.

Various coals in powder exposed to the air at 200° C.
Time in days. Ordinates, weights. Abscissæ times.

coal would stand it, at 400° C. The whole forms, to the best of my knowledge, the most complete set of data ever scientifically co-ordinated for the solution of a single technical problem.

An attempt was then made to analyse the curves of variation of weight with the following result:—

FIG. 4.

Commentry coal in powder exposed to air at 200°. Components of the curve of variation of weight.

and it was shown that the contents of iron, sulphur, phosphorus, &c., could not in any way account for the magnitude of the variations noted.

The inflammability of coal after exposure to various temperatures was tested by trying whether fragments could be lighted by a candle, and also by heating samples of various grades of division in the stoves till they took fire. Both sets of experiments led to the same result, viz., that the inflammability is highest with lignite, and passes through gas coal and coking coal to anthracite in the order named, but the differences between the gas and coking coals were not great. This is a point of some importance in connection with spontaneous fires, for there has, I believe, been a tendency to make too much of supposed great differences in the natural tendency of coals to inflame spontaneously.

Summing up, Fayol declares that the necessary and sufficient condition to preserve coal unaltered in storage is to keep it from the action of the air, and points out that this can be most thoroughly done by placing it in air tight bins, or immersing it in water. As either of these methods is practically impossible on account of the cost, the next best thing is to pile the slack (which is chiefly in question) in heaps as deep as possible, bearing the

liability to spontaneous fires in mind. At Commentry it is possible to keep the slack in heaps 2 m. deep without starting fires.

Having established the principles, Fayol then proceeded to consider the phenomenon of spontaneous fires in detail, both by investigating the conditions under which they occur in heaps of coal in the air and by experiments on considerable quantities of coal exposed to a series of graded temperatures.

The facts established with regard to heaps of coal in the air are summed up by Fayol as follows—at all events as regards the Commentry coal:—

1. Large pieces and smaller ones which will not pass a sieve of 20 mm. diameter do not get spontaneously hot. No appreciable heating has ever taken place in more than 200 heaps of such coal of from 3 to 6 m. in height.

2. The slack passing a sieve of 20 mm. diameter heats and fires spontaneously whenever it is in large enough heaps. The raw slack is rather more inflammable than it is after it has been washed.

3. The through coal as raised behaves like the slack.

4. The coal in fine powder coming from the slack washing is a little less inflammable than the screened slack. When this powder contains much clay it is less inflammable. This is also true if a large quantity of pyrites is present.

5. The carbonaceous schists, obtained by picking out, fire like slack.

6. The schists resulting from the washing contain much clay and are much less inflammable.

7. Heaps formed of inflammable coal or schist built up very slowly by successive layers of about 1 m. depth do not fire whatever the final volume may be.

There is a direct relation between the liability to spontaneous heating and the height and volume of the heap in which it occurs. If the heap is small the temperature rises to a certain point, after which it becomes stationary, and then falls again. There have been no cases of spontaneous fires in heaps of less than 2 m. height—on the other hand, when the height passes 4 m. spontaneous combustion always occurs.

The N.S.W. Commission came across and verified for themselves a similar piece of evidence in regard to the influence of the depth of the heap. The engineer of the Australian Gas Light Co., of Sydney, N.S.W., drew the attention of the Commission to a fact he had noticed in connection with the coal stores belonging to his company. In one of these stores the coal was never more than 14 ft. 6 in. deep, in the other it was 20 ft. deep. The coal stored at both stores was exactly the same. The heap 14 ft. 6 in. deep never fired, but the 20 ft. heap was always hot and generally on fire at one or more points.

Fayol has studied experimental heaps of Commentry slack in a most thorough manner. One experiment is so thorough and conclusive that we may profitably consider it in greater detail. A heap of newly-won slack was thrown up, having the following dimensions:—Length, 40 m. (131 ft.); height, tapering from 6 m. (20 ft. nearly) to nothing; breadth, at the top 1 m. (3 ft. 3½ in.), at the bottom depending on how the coal tailed out.

The temperature was tested at about ten separate points every day during ninety days, and the results are set forth in the diagram 4 (copied from Fayol's paper), and referring to Commentry slack. It was ascertained that the highest temperatures occurred in the median plane, parallel to the length of the heap; and the temperature was therefore tested in this plane.

Fayol's conclusions are as follows:—1. Where the layer of slack is thin there is no rise of temperature. 2. The temperature at any time increases with the height of the heap, i.e., as we pass along the heap from the lowest to the highest points there is a continuous rise of temperature in the coal. 3. At a height of about 3 to 4 m. (10–13 ft.) the temperature rises steadily at first, and finally falls without ever passing 60° to 70° C. (140° to 158° F.). 4. At or about a height of 4 m. (13 ft.) the temperature continues to rise. During the third month, or thereabout, steam begins to rise from that part of the heap whose height is greater than 4 m.; this is followed by the appearance of a colourless gas, smelling strongly

Diagram No. 5.

Rise of temperature in heat of Small Coal exposed to atmospheric influence.

Time of Exposure to the Air (in days).

Explanatory Note.

The sections show the temperature of the coal at various points in the heap after standing for 90 days in the air.

The curves illustrate the rise of temperature at the points indicated by the numbers, whose situation can be ascertained from the section.

of petroleum; and within a few days thereafter smoke is seen to issue from the sides of the heap. The point at which the smoke is first observed is generally half-way up the side of the heap, at the place where the heap is highest. At the moment when this appears, sections of the heap along the median line, and perpendicular to it at the highest point, disclose the existence of three zones:—Firstly—A lower central zone, where temperature lies between 120° and 150° C. (248° F. and 302° F.). Secondly—A zone surrounding the former, but at a considerably lower temperature. Thirdly—The exterior zone, which is approximately at the temperature of the air.

If the heap is cut across, so as to expose the core of the first zone, yellow and white fumes are rapidly given off; the temperature rises quickly to 200° C.—300° C. (392°—572° F.), and ignition takes place.

From whatever part of the mine the coal was taken, whatever was its ash content, and the nature of the ash, the coal heaped in the open air underwent the same thermal changes, which followed an approximately constant law. Atmospheric influences, hot and cold, drought and damp, had either no influence on the progress of events, or an influence too small to be observed; and the same remark applied to the impurities in the coal."

Another particularly instructive experiment by M. Fayol was the following:—A large bell jar (like a small gasometer) working into an annular water-pit was provided. The bell was 2.15 metres (6 ft. 7 in.) in diameter, and 1.2 metres (4 ft.) high. The coal was heaped up on the ground below the bell, and by raising the latter air was admitted, while by lowering it into the pit air was shut off. Air could also be let in, in any desired quantity, by opening air-holes near the bottom and top of the bell. In this manner the dependence of the temperature changes on the air supply was ascertained. In these tests five representative kinds of coal were employed, and each was tested under the bell after being initially heated to 75°, 100°, 150°, and 200° C. The general result of the experiments was as follows:—1. If the bell is closed the coal gradually cools to the air temperature. 2. If the air-holes are slightly opened the temperature rises, and spontaneous combustion occurs. 3. By alternately opening and shutting the air-holes the temperature can be caused to rise and fall.

FIG. 6.

Coal alternately exposed to and protected from the action of the air.

Time in days

By adjusting the air-holes properly it is very easy to get the coal to fire.

With regard to the effect of the size of the particles the result is so important that it had better appear in M. Fayol's own words:—"These experiments succeed easily with coal in grains deprived of dust, fairly easily with larger grains, and with greater difficulty with ordinary slack. In the last case the fine coal-powder which fills up the space between the fragments offers an obstacle to the penetration of the air." By regulating the air supply of the bell it is easy to cause coal to fire which would not do so if exposed at the same initial temperature to free air.

Finally, Fayol made similar experiments on a large number of coals, though on a smaller scale, by placing the coal in air at various temperatures. In general, three sizes of samples were tested:—1. 50 grms. in a crucible. 2. A sample in a brass box measuring 12 by 12 by 3 c.m. (4.7 in. by 4.7 in. by 1.2 in.). 3. A sample in a cubical brass box measuring 12 c.m. on the side. From these experiments Fayol gives the relative inflam-

mability of coals when exposed to hot air, i.e., at temperatures of 75°, 100°, 150°, and 200° C. (167°, 212°, 302°, 392°, and 752° F.):—Lignite (most inflammable), gas coal, coking coal, anthracite (least inflammable).

The general conclusions from the very large number of tests made are as follows:—These conclusions refer to samples of coal placed in hot air, in greater and smaller masses, and in various states of fineness of division:—1. Combustion takes place more rapidly the higher the temperature to which the coal is exposed. 2. At 400° C. (752° F.) all the samples fired—anthracite after some little time, lignite at once. 3. At 200° C. (392° F.) anthracite only fired when in grains, and bituminous coal only in the larger samples. 4. At 150° C. (302° F.) lignite in powder was the only one which took fire when exposed in the masses experimented upon.

The effect of the state of division of the coal was also tested in a similar manner with interesting results. In general, the finer the powder to which the coal was reduced the more rapidly did it take fire; and a single fragment of slack did not fire so readily as a number of fragments placed together. With regard to the temperature at which the coal took fire, the following approximate results were obtained, referring to coal in powder:—

	° C.	° F.
Lignite	150	= 302
Gas coal	200	= 392
Coking coal	250	= 482
Anthracite	above 300	= above 372

Too much stress must not be laid upon these exact values, because small differences in the conduct of the experiment lead to considerable variation in the results.

In order to study the progress of spontaneous heating in small samples of coal, the coal was raised to any desired temperature, and then exposed to the air in heaps 1.5 m. (say 4 feet) high, and containing 4 cubic metres (or 5.2 cubic yards). The conclusions from the tests were as follows:—1. If the heap was made in the open air with coal which had been previously heated to a little above 100° C. (212° F.) fire generally broke out in the course of a few days. 2. When the initial temperature lay between 60° and 100° C. (140° and 212° F.) there was sometimes a rise and sometimes a fall in temperature. 3. Below 60° C. (140° F.) the coal always cooled down to the air temperature.

A study of the circumstances leading to spontaneous combustion was then made by Fayol on the supposed influence of moisture in promoting spontaneous combustion. Fayol sums up his experience as follows:—"The influence of wet weather on heaps of coal has not been sufficiently marked to be observable."

On the other hand, there is no doubt a floating opinion among people accustomed to the handling of coal to the effect that moisture does increase the tendency to spontaneous combustion. In a letter to the English Commission in 1876, Mr. Poole, Inspector of Mines, Nova Scotia, makes the following remark:—"Heat has been observed in piles of slack coal that have been accumulated during the summer for the use of engines during the winter, when the season has been showery, but not when it has been dry." This evidence is very direct and absolutely opposed to Fayol's experience, and a good deal of similar evidence was tendered to the English Commission: for instance, out of 26 answers to questions as to the effect of moisture, every reply was to the effect that moisture was a source of danger. An examination of the reported evidence shows that in every case (with the above exception) this was a matter of impression merely. Cross-examination of a number of witnesses before the New South Wales Commission, who held this opinion, convinced me that it was in general held on very slender grounds; and two cases in which rain had apparently increased the tendency of the coal to heat were otherwise explained. Nevertheless, if the coal contains pyrites in any quantity this substance will be decomposed by air and moisture under circumstances under which it would not be decomposed by either agent separately. Since the products of decomposition of pyrites tend to crystallise and in general occupy a greater volume than the pyrites itself, it is clear that the "weathering" of pyrites may have an

indirect influence favouring spontaneous combustion, by causing the coal to break up into small fragments, which, as we have seen, heat more readily than larger ones.

Fayol made some experiments on the subject by building heaps of coal containing 2 to 12 cubic metres, placing them under cover, and watering some of them, while he kept the others dry. In no case did the rise of temperature exceed 60° C. These experiments leave much to be desired, (1) because they were only made on one class of coal low in pyrites; (2) since the temperature of the heaps never rose above 60° C., it is impossible to say how near they were to the critical condition above referred to; and (3) Fayol is careful to guard himself against any generalization of the result obtained.

The chief bugbear in connection with the spontaneous heating of coal has from the beginning been the question as to what part, if any, is taken by pyrites, and this must be considered as well as we can before a general theory of the phenomenon can be formulated. The stability of iron disulphide as it occurs in coal is probably a very variable quantity, and it would possibly be worth while to make a comparative study of the matter so as to obtain precise data which at present are lacking. We have already seen that neither Richters nor Fayol were able to detect any effect as regards the oxidation of their respective coals by their respective samples of pyrites, but it may be argued that, had they happened to use the coal brasses of South Staffordshire for instance, the results would have been different. One point to be noticed is that the quantity of water required for the decomposition of iron disulphide is not negligible. The equation, $2\text{FeS}_2 + 2\text{H}_2\text{O} + 7\text{O}_2 = 2\text{FeSO}_4 + 2\text{H}_2\text{SO}_4$, requires that water shall be present to the extent of 15 per cent. of the weight of the pyrites, and the sulphuric acid would also take up a considerable quantity. I have been informed by Mr. A. E. Savage, a well-known Australian metallurgist and a member of the Second N.S.W. Commission on the Spontaneous Combustion of Coal, that at the Mootooroo mine in South Australia there was a form of pyrites which rapidly decomposed, forming a pungent dust even in the exceptionally dry air of that district. It is difficult to understand how this could happen unless some other base was present to take up the excess of sulphuric acid. It is easy to see, however, on the other hand that if a trace of sulphuric acid once did get formed it would collect water to keep the reaction going out of even very dry air. No doubt the pyrites in question was a marcasite, and the same observer at the same time reminded me that the late Mr. Cosmo Newbery of Melbourne experimented on the large scale for years with the auriferous mundie (pyrite) of the Victorian quartz reefs in order to try to get it to weather so that the gold might be extracted—but never succeeded in making it break up. Of course, it is well known and stated in all the books that the cubical form of pyrites is much more stable than the rhombic—or marcasite—form; but even among marcasites themselves there are great differences in stability—the fibrous brasses, for instance, being possibly less stable than the lamellæ of pyrites found in most coals.

In regard to the heat of oxidation of pyrites the following calculation is of some interest for our purpose; it is applied to one of Richters' experiments the analytical data of which are available. Temperature of oxidation, 190° C.; time, 10 hours in a slow stream of air; loss of hydrogen, 0.66 per cent., and of carbon 1.25 per cent., on the weight of the coal. I calculate that per 100 grms. of coal this would mean at the very least the liberation of about 30 kilogram calories, or say 15–16 kilogram calories per 1 per cent. oxidation, and probably three or four times as much. If the coal contained 1 per cent. of pyrites, we should only obtain at the outside 2.7 kilogram calories from its oxidation if the sulphuric acid remained free. This might perhaps be increased to 3.5 kilogram calories if the acid combined with some base. If we take the specific heat of coal at 0.2, then the oxidation of 1 per cent. of its weight of pyrites might give enough heat to raise its temperature from 0° to 175°, while the oxidation of the carbon and hydrogen would give a temperature rise of 750° at least, and probably several times this amount; so that, weight for weight,

the oxidation of the coal is vastly more effective than the oxidation of the pyrites.

I have attempted to obtain some data for the effective specific heat of air dry coal, by crushing it till the largest remaining fragments measured about 2 mm. on the side and then heating it to about 80° C. in samples of from one to two pounds, and mixing it with about its own weight of water at a lower temperature. The specific heat appeared to vary from 0.35 to 0.45 according to the length of time occupied in heating the coal powder to the upper temperature. The experiment is not easy on account of the low heat conductivity of powdered coal; the powder must be kept well stirred if anything like a correct estimate of its temperature is to be obtained. The experiments were only rough, and I do not insist upon them, but I think they show that the effective specific heat of coal still containing moisture is near 0.4 than 0.2.

Given a mixture of coal and pyrites, both oxidisable in air and both reactions being accompanied by an evolution of heat, it is of course impossible to demonstrate that a spontaneous fire in such a mixture should not have been assisted by the presence of the pyrites. Some considerations appearing below show, however, that it is in general unlikely that the presence or absence of pyrites has any appreciable influence. The question of the action of pyrites in promoting spontaneous combustion can, however, be easily examined experimentally for any given coal and under any prescribed conditions. To do this it is only necessary to make a heap big enough to heat spontaneously and as the heating progresses to follow by analysis—conveniently by sulphuric acid estimations on properly chosen samples of the coal—the connection (if any) between the decomposition of the pyrites and the rise of temperature of the coal. If it is worth while the heap can be surrounded by walls of heat insulating material and the heat generated could possibly be estimated by making suitable allowances for the loss by conduction and by air currents, and this heat can be compared with the thermal change incident on the decomposition of the pyrites as revealed by analysis. In an enclosure, with air inlets and outlets which can be regulated, the variation of the percentage of carbonic acid gas in the air at the exit holes can also be followed—bearing in mind Richters' data on the subject.

If a trial cannot be made—and except in special circumstances it would rarely be worth while to make one—we have to fall back on general principles, and from these it appears that coal cargoes seldom or never fire through the action of pyrites, and for the following reasons:—
1. The cases of spontaneous firing under experimental conditions observed by Fayol were found to be independent of the quantity of pyrites present. 2. The laboratory experiments of Richters', so far as they go, lead to the same result—though an entirely different coal was used. 3. Experience shows that pyrites is generally stable in air, i.e., unless liquid water is present. But it will be shown that spontaneous fires have often, indeed generally, occurred in cargoes of dry warm coal. 4. No connection has ever been traced between the pyrites content of coal and the frequency of fires. The N.S.W. Commission No. 1 made every effort to bring such an effect to light assuming it to exist, and did not succeed in doing so—in fact, the data were such as to indicate that no relation existed. 5. In Commentry coal, proved by Fayol to fire as a result of direct oxidation, it was found that a mixture of fragments and dust was the most dangerous, i.e., would fire sooner under favourable conditions than any other screen gradings of the same coal. But such a mixture is formed in a coal cargo under the hatchways and nowhere else—and is produced by the breakage of the coal in loading where it is dropped down the hatchways under conditions which allow the large pieces to roll away and the dust and slack to form a heap. The N.S.W. Commission No. 1 obtained a considerable body of reliable evidence as to where fires originated in coal cargoes, and thus discovered that they invariably started under one of the hatchways. Similar evidence convinced the Royal Commission of 1876 of the same fact. The spontaneous heating of coal at sea therefore occurs under

actly the same physical conditions as determined flammation in Fayol's experiments—and in the latter influence of pyrites was inappreciable. It is difficult believe, therefore, that pyrites can have much effect one of these entirely parallel cases when its influence known to have been negligible in the other. 6. The ay in which the temperature rises, i.e., the temperature me curve of a spontaneous fire at sea has been often, ough roughly, ascertained by means of thermometers. ayol and the Second N.S.W. Commission, however, ve recorded the same phenomenon in the experiments i heaps, and the general progress of the heating is the me in both cases. It would be strange if one referred pyrites and the other to the direct oxidation of coal. Fayol states that "the influence of wet weather on eaps of coal has not been sufficiently marked to be ervable," but if pyrites of all ordinary varieties had me in question as a source of heating there is no doubt at wet weather would have helped the heating. The .S.W. Commission No. 2 definitely proved that wetting 50 tons of coal containing 0.5 per cent. sulphur, mainly pyrites, prevented it from rising above 40°–50° C., hile 250 tons of dry coal of exactly the same kind exposed nder exactly similar circumstances rose to 135° C. in out six weeks and was only kept from firing by digging at. 8. The spoil heaps in mines, often containing a eat deal of pyrites, in some cases nearly as much pyrites coal, so far as I am informed, generally fire where ey are dry, not where they are damp. This at least as been true of the limited number of cases which have me to my notice: cases of firing in pillars also occurs here the coal is dry. 9. It was suggested by Sir nderick Abel and Dr. Percy in the memorandum preared for the Royal Commission, 1876, that pyrites ight have some influence in promoting the disintegration of the coal if the cargo was wet, and thus in preparing e mechanically for spontaneous heating. This is true, ut as fires start under hatchways where the coal is roken by impact in any case to a far higher degree than could be broken by pyrites—it is clear that the above ggestion has no real application.

Perhaps we may sum up the matter with the remark that sufficiently formidable array of evidence can be collected i favour of Richters' view as to the origin of spontaneous es to justify us in neglecting the influence of pyrites i forming a general theory of spontaneous combustion. his we may now proceed to do on the basis of Fayol's nd Richters' proof that the bituminous constituents of al oxidise in air at all temperatures, but with enormous celeration as the temperature rises. The heat liberated uring this oxidation is high (see page 762), and coal is n extremely poor conductor of heat and has an effective ecific heat which we may perhaps put at about .35. he most important of these factors is possibly the low ermal conductivity of coal. The conductivity of coal i solid slabs is very low—of the same order as wood nd paper (Landolt and Bornstein Tabellen)—but, of ourse, the effective conductivity of a heap of slack is ery much less. A witness wrote to the 1876 Commission, mentioning that snow that had fallen while a heap of coal as being formed often lasted over the following summer— nd I have been informed by a gentleman who was resent when this paper was read, that a case has been nown of snow lasting under a heap of coal for two years— ut in neither case was the size of heap and depth of al stated. My own experience, moreover, has convinced e that a heap of slack has an extremely small thermal onductivity. If, therefore, a heap of coal be exposed o the air at any temperature it must oxidise, and heat ust be generated, and moreover this heat cannot escape o any extent by conduction through the coal. The emperature time curve of the hottest part of the heap ill depend on the relation between the heat generated nd the rate at which it can be dispersed by radiation, onduction, and air convection—the last of which may e expected to be by far the most important. Unless air an penetrate the heap fast enough to bring fresh oxygen o the centre as soon as the existing supply is used up idation will stop and the heat generated will diffuse utwards. If the temperature in the heap be above

that of the air outside the heap, air will tend to circulate through the coal. If the air current is large enough or increases fast enough with rise of temperature, heat will be abstracted from the heap nearly as fast as it is formed and the temperature can only rise slowly: meanwhile the more easily oxidisable constituents in the most favourably situated places will be getting used up, or, at all events, the activity of the coal in absorbing oxygen will, as Richters, has shown, diminish. It can be foreseen therefore that in this case the temperature of the heap will rise slowly to a maximum, and then fall away as weathering progresses.

On the other hand, if the heat insulation be sufficient, and if enough air be allowed to enter the heap to supply the necessary oxygen—but not enough to act as a cooling draught—the temperature of the heap will rise faster—the oxidation proceed more rapidly and the temperature will rise continuously till the firing point is reached. It is evident that for a spontaneous fire to originate, a good many conditions must be simultaneously satisfied—indeed, it would be a most risky proceeding to attempt to produce a spontaneous fire for the purposes of a lecture demonstration unless the exact conditions had been ascertained beforehand by careful preparation. If the experiment were to be made on a cargo of coal we should have to attend in minute detail to the air supply to the coal—to the initial temperature of the coal—to its volatile carbon content—to the moisture—to the mean temperature of the air and sea during the voyage—to the size of the cargo—to its depth—to the degree to which the favourable mixture of dust and smalls accumulated under the hatchway—and to the duration of the voyage. With so many variables it would hardly be possible to arrange for two cargoes to be shipped and carried under conditions exactly similar in all respects, and yet a slight variation anywhere might determine whether the temperature would rise to a maximum and then decline, or rise indefinitely. To a superficial analysis of the conditions attending the loading and carriage of coal it might appear that some cargoes fire and others do not, capriciously—and this, in fact, was the great difficulty at the commencement of the inquiry—there was at first no clue to the mystery of why certain cargoes fired while others "loaded and carried under identical conditions" escaped. Thanks to Fayol it becomes possible to understand how small a difference existing between reported "identical conditions" is sufficient to explain why some cargoes fire and others escape.

The second N.S.W. Commission has recorded very fully the progress of spontaneous heating in two heaps of coal contained in bins which were not air-tight. The experiment was made to ascertain the exact effect which thorough wetting has on the spontaneous heating of coal, and as temperature and other observations were very fully carried out, we may make use of this investigation in order to have the facts of a spontaneous fire fairly before us. The coal was slack from the main seam at Newcastle, N.S.W., and was chosen as representing the coal of the district. At the close of the experiment, when the bins were emptied proper samples were made and the following sieve tests made:—

	Dry bin.	Wet bin.
Remained on 2-mesh sieve	30.20	36.81
Passed through 2 and stood on 4-mesh	24.49	21.76

	100.000	100.000

* The coal as loaded into the bin contained 2.2 per cent. of moisture.

† Analysis after the coal had been dried at 100° C.

Coking tests on mixtures of coal dust and sand, graded in each case to pass 60 mesh and stand on 100 mesh sieve, were made by placing the mixture of coal and sand in a one-inch covered porcelain crucible and heating over a kerosene blast furnace for 1 hour—the bottom of the crucible being just red. The cone of coke was then placed on a table and pressed by a thin steel spatula as usual—with the result that mixtures containing over 80 per cent. of sand could not be regarded as coherent—the cones breaking down with a spatula deflection of about one-half inch.

Description of bins.

In view of the known importance of ventilation and removal of heat by atmospheric influence in connection with spontaneous heating of coal, it is necessary to describe the construction of the bins at some length.

Each bin was constructed so as to contain a cubical mass of coal, the length of each side being approximately 21 ft. The walls were constructed of old planks, averaging 6 in. wide by 1 in. thick, supported externally by a rough timber frame, well strutted to resist the outward pressure of the contained coal. The lining planks being of somewhat irregular shape, there were numerous spaces between them, which, though too small to allow coal to pass, permitted a certain amount of ventilation over the whole external vertical surface of the bins. To protect the coal from rain and sun, a flat galvanised iron roof was provided, supported on short uprights from the main frame of the bin at a height above the level top of the coal of from 4 ft. on the north-west side to 7½ ft. on the south-east side. The sides of the bins between the coal and the roof were closed with boards sufficiently to prevent the entrance of rain, but not too closely to prevent free ventilation.

The two bins were separated from one another by an air space of about 9 in. between the walls. This space was not open at the bottom or sides, and there was consequently no free circulation of air, but it was sufficient

to give good heat insulation between the two masses of coal. Two sides of the structure were entirely exposed to the weather, but on the south-east side (that on which the coolest winds prevail) it was protected by a railway embankment nearly as high as itself, and the space between it and the embankment was filled in with coke during the whole time the experiment was in progress. On the south-east side there was also a pile of coke almost as high as, and close to, the bins. It was on this side that the wet coal was situated.

The coal was filled from the railway trucks into wheelbarrows, and tipped from these directly into the bins at several points over the area of the floor. The height from which the coal fell was at first 17 ft., gradually lessening until the bins were full. The two bins were filled as nearly as possible at the same time, and as each barrowload of coal was dropped it was spread with shovels over the surface of the coal already tipped, thus avoiding, so far as possible, the separation of the fine from the coarse coal. If the coal had been tipped at one point only and not levelled, a conical heap would have been formed, down the sides of which the larger pieces of coal would have rolled fastest and accumulated at the bottom.

When loading the coal into the "wet" bin, a stream of fresh water from a hose was continuously played over it in such a way as to thoroughly saturate it. The quantity of water used was sufficient to cause a small stream to flow from the bottom of the bin, but not sufficient to wash out any considerable quantity of fine dust.

An experiment which I have recently made on fine slack shows that the maximum quantity of water which can be held for 12 hours by a bucket of coal—the bucket having a perforated bottom—is about 14.5 per cent. of the weight of the dry coal, or 12.7 per cent. on the mixture of coal and water. On the other hand, coal containing three-quarters of the above maximum would be described as thoroughly soaked; this would then contain about 11 per cent. of water removable by air drying at ordinary temperatures.

For the purpose of taking temperatures, 13 thin galvanised iron pipes of about 2 in. in diameter and 0.018 in. (0.457 mm.) wall thickness, were placed vertically in each bin prior to loading, and were situated as shown in the diagram.

Diagram No. 7.

Plan of Bins.

The numbers refer to the thermometer tubes.

The impact of the coal in loading slightly displaced these pipes, but not to any serious extent, except in the case of two of them—No. 3 in the dry bin and No. 5 in the wet bin—which became obstructed so as to prevent temperatures being taken below 16 and 8 ft. respectively from the surface.

It had been foreseen that this might happen, in spite of all precautions to the contrary, but we were afraid to use any but very thin pipes, since it was the object of the experiment to ascertain the distribution of temperature in a heap of coal under normal conditions, and it was therefore important that this distribution should not be affected by circumstances peculiar to the experiment. If the walls of the tubes had been thick, the vertical distribution of temperature in the tubes would have depended appreciably upon the conductivity of the tubes themselves, as well as upon the distribution natural to the coal, and the object of the experiment would not have been attained.

Methods and records of observations.

The bins being full on Dec. 2nd, 1908, the first temperature-reading was taken on Dec. 10th by centigrade thermometer. The subsequent readings were taken at intervals shown by the temperature records. The temperatures recorded are the mean of two and sometimes three readings at each point. The reason for taking more than one reading was not because there was any extensive variation, but more as a check on the accuracy of the observer. The observed readings were corrected to the true temperatures by a table of corrections supplied with the thermometers from the Physical Laboratory of the Sydney University. The corrections resulted from a comparison of the thermometers used with the standards, whose changes had been studied. The thermometers were enclosed in copper cases, both for the protection of the instruments and to provide a mass of metal to retard variation in temperature while the thermometer was being drawn to the top of the tubes for observation. Experiments were made to determine the fall of temperature in the time usually required in pulling the thermometer to the top of the tube, but this being found inappreciable, no correction was applied.

The temperatures were taken at two alternate sets of levels on alternate days, as is shown by the temperature records, until towards the close of the experiment, this being rendered necessary by the inability of the observer employed to take the temperatures at all the points of observation in any one day; as it was, each day's work consisted of 156 readings. The curves are, therefore, perhaps not quite as representative as they might have been had observations been more frequent. It would,

FIG. 8.

DRY AND WET BINS.

Maximum, minimum and mean temperatures, in degrees Centigrade.

perhaps, have been appreciably better had there been daily readings in each pipe at each level, at any rate when the temperatures began to rise rapidly, but this was impracticable under the circumstances.

The first temperature readings taken on Dec. 10th showed a mean temperature of 39.8° C. in the dry and 28.9° C. in the wet bin, a difference of 10.9° C., due to cooling by the water and also to evaporation from the extensive surface of wetted small coal during the prolonged loading of the bins. That it was due to more rapid spontaneous heating of the dry bin seems improbable, in view of the slow speed of the rise of temperature recorded immediately subsequent to this date. With regard to the weather conditions, nothing abnormal was observed during this period.

When the temperature of the coal in the "dry" bin began to rise, it increased very rapidly (precisely as in the experiments of Fayol) until February 13th, when at 8 ft. from the surface in the centre tube the temperature was so high as to melt the solder connections of the thermometer and char the string that was used for raising and lowering it, thus causing the instrument to fall to the bottom of the tube. After the loss of the thermometer a cord was lowered into the tube and left for a short time, and on being drawn up was found to be charred at a point half-way through the coal, and indicated by its appearance that the temperature was highest at about 8 ft. from the surface.

DRY BIN.

Temperature of centre pipe at different levels.

In view of this decisive result and the inflammable nature of the bin and its surroundings, on Feb. 13th it was decided not to risk a fire by prolonging the experiment. The dry bin was therefore flooded with water and unloaded as far as was necessary to remove all the hot coal. Before unloading there was no visible smoke, though there was a distinct, but not strong, smell of the gaseous products of distillation of coal. On digging down, the heat seemed to be confined to a spot immediately in the vicinity of the centre pipe. No visible amount of coking had taken place, and the bulk of the coal was not to be distinguished by its appearance from fresh coal. After the heated part of the coal, and such as fell in from the sides during digging down, amounting altogether to about one-third of the whole, had been removed, the bin was left to itself, and showed no subsequent signs of heating.

The "wet" bin gave absolutely no indications of heating beyond the slight rises of temperature shown in the thermometer records, and from Jan. 27th there was a steady decline in the mean temperature. Minor variations of temperature at particular points in both bins probably correspond to variations in ventilation depending on changes of direction of the wind, &c.

Two of the most important results noticeable in these curves are the great cooling effect of the water on the coal and the relatively long period during which the temperature of the dry coal rises comparatively slowly. It might be supposed that the effect of wetting the coal was confined to reducing the initial temperature to such a point that heating was delayed till the weather cooled down. This, however, is not the case; for the wet coal did rise above the initial temperature of the dry coal, and the air temperature at the close of the experiment was practically the same as it had been throughout.

The importance of having the coal cool to begin with if a fire is to be avoided say for 90 days is rendered evident by the form of the curve of rise of temperature in the dry bin.

Applications to the phenomena of spontaneous combustion of cargoes of coal.

If the principles established above are correct, we should expect that liability to spontaneous fires would depend on the following conditions:—

1. *Size of cargo.*—The larger the cargo, the larger and deeper the ship; consequently, the percentage breakage on loading will increase with the size of the ship, and the size of the heap of dust under the hatchways will vary as the fourth power of the linear dimensions of similar ships. This is on the assumption that all large ships have the same number of hatchways and that the dust is substantially produced by the breakage in loading into the ship. The Commission of 1876 drew attention to the influence of size of cargo on percentage of casualties in the following words, alluding to the statistics collected: "Again this return shows, to a startling extent, that the proportion of casualties traceable to spontaneous combustion increases *pari passu* with the tonnage of the cargoes. This becomes still more apparent when the European trade is deducted. The return then shows that there were, in 1874:—2,109 shipments with cargoes under 500 tons, in which 5 casualties occurred,—or under $\frac{1}{4}$ per cent.; 1501 shipments with cargoes between 500 and 1000 tons, in which 17 casualties occurred, or over 1 per cent.; 490 shipments with cargoes between 1000 and 1500 tons, in which 17 casualties occurred, or $3\frac{1}{2}$ per cent.; 308 shipments with cargoes between 1500 and 2000 tons, in which 14 casualties occurred, or over $4\frac{1}{2}$ per cent.; and 77 shipments with cargoes over 2000 tons, in which 7 casualties occurred, or 9 per cent. The casualties in vessels bound to San Francisco were the most remarkable. Deducting vessels under 500 tons (in which no cases of spontaneous combustion were recorded), the return shows 9 casualties out of 54 shipments. These also increase in proportion to the tonnage of the cargoes, till we arrive at the alarming fact that out of the five ships with cargoes of over 2000 tons sent to San Francisco in 1874, two suffered."

The N.S.W. Commission found a similar relation as shown in the following diagram:—

Diagram No. 9.

Illustrating Heating of Cargoes in (classified) ships which sailed to American Ports.

Years 1888—1896.

Orlinates: Percentage of Casualties.

Abscissa: Magnitude of Cargoes.

2. *The heap of dust under the hatchways should be the most dangerous place.*—Evidence of this was given to the 1876 Commission, and the N.S.W. Commission failed to find a single undoubted case of a spontaneous fire having occurred originally in any other place.

3. *Slight ventilation should be dangerous.*—It was formerly the practice to ventilate coal cargoes by means of air trunks running along the bottom of the ship below the coal. Air was supplied to this system by more or less elaborate vertical shafts, and escaped into the cargo by lateral openings so as to distribute itself through the coal. The Commission of 1876 proved that in this way the carriage of coal was made more dangerous. Their finding was as follows:—

"Of the 70 ships that suffered in 1874 none are reported as not having been ventilated, while 38 are distinctly stated to have been ventilated, 35 of them being vessels over 500 tons. But the most startling illustration is furnished by the cases of four vessels, the 'Euxine,' 'Oliver Cromwell,' 'Calcutta,' and 'Corah.' These ships, to which reference was made by several of the witnesses who appeared before us, were loaded under the tips at Newcastle, at the same time, with the same coal, and from the same seam, sometimes one ship being under the tip and sometimes another. They were each carrying from 1500 to 2000 tons of coal. The 'Euxine,' 'Oliver Cromwell,' and 'Calcutta' were bound for Aden; the 'Corah' for Bombay. The first three ships were thoroughly ventilated; the fourth was not ventilated at all. The 'Euxine,' 'Oliver Cromwell,' and 'Calcutta' were all totally lost from spontaneous combustion. The 'Corah' carried her cargo safely to Bombay." Nevertheless, if the ventilation had been thorough it would have kept the coal cool. An illustration of this is contained in a communication made to the Commission of 1876 by Captain Henry F. Scott, of Newcastle-on-Tyne. This communication gives such a good idea of what a spontaneous fire on board a sailing ship means, and is so evidently the narrative of a brave and resourceful man, that it is well worthy of quotation. It will also serve to give an idea of the subject to those who have not been fortunate enough to listen to many similar stories as they have been unfolded before Royal Commissions and Courts of Inquiry:—

"In 1852 I took a cargo of coal from Sunderland to Madras, without ventilators. After passing the Cape, not having been able to take off hatches for a considerable time owing to bad weather, I was alarmed at finding

oke issuing from the cargo, with a strong smell of
ipient gas. In this dilemma a panic came over my
w, and they insisted on getting the boats out and
paring to leave the ship. Now as danger and necessity
en sharpens the wits, after looking at things in all their
arings I determined to try and save ship and life
ewise. After a little trouble in getting my men to
ond me in my plans, we went to work. Happening to
ve on board some rod iron, I roughly pointed a few of
bars and drove them down into the cargo in different
ections. Allowing them to remain awhile, we drew them
t, feeling them all their length with the hand, marking
the hottest parts with chalk. By driving them down in
directions from the main hatchway, I found
at the heat was all in one place forming a nucleus
about 10 ft. in the lower hold and directly
der the hatchway, the bars driven diagonally through
a coal coming out quite cool. I then got four
adding-sail booms roughly squared, and knocking down
lkheads and part of bulwarks to procure boards, we
ade a trunk about 16 ft. long, 2½ ft. square at the upper
d and 3½ ft. at the lower, in form of a square cone.
e then dug down as far as we could, and placed the large
d of the cone in the hole, with a man inside, who dug
t the coal from under it, driving the cone down from
e top as the hot coals were sent up in buckets. After
tting down about 7 ft. we came upon the coal so hot
at the man at the bottom could only remain a short time,
ad had to be replaced at short intervals, owing to the
eat heat and smoke, and putting his feet into wooden
oxes which we made to save from burning them. We
ow found that as fast as the coal was cleared from the
ottom, the trunk crept down without forcing, owing to
s conical shape and the rolling of the vessel. In six
ours we had it down to the keelson, and by removing
ch alternate board from the side of the trunk at the
otest part, we grubbed out great part of the coal which
as smoking, and would not have been long before taking
re. I then rigged a topmast studding sail as a wind-sail,
ring the foot of it round the top of the cone, and thus
ring a strong current of air down to the bottom and
rough the sides where the boards were removed, and
about 24 hours, on going down our pit, we had the
expressible pleasure of finding the temperature little
ore than milk warm, and by continuing the use of the
indsail all heat and smoke disappeared, and ignition was
vented just in time. On two subsequent occasions I
ave repeated the process, and always found it successful.”
Captain Scott then goes on with the most absolute good
ith and assurance to recommend his system of thorough
entilation as a preventive of fires at sea. If the reader
mpares this very direct opinion, well supported by
vidence, with the equally direct and opposite evidence
dduced by the Royal Commission, and quoted above,
nd if he recollects that a large number of equally credible
itnesses, with equal assurance and with equal good faith,
ere present on both sides—ho will possibly realise the
ifficulty of trying to arrive at a conclusion without a
nowledge of the physics and chemistry involved. Indeed,
without the key supplied by Richters and Fayol, the
uestion might be fairly regarded as insoluble—and was

so regarded by many responsible but unscientific people
for many years after the work of these investigators
had been published.

4. *The risk of a spontaneous fire is much greater when the
cargo is loaded in summer than it is when the cargo is loaded
in winter.*—This was first established by the N.S.W. Com-
mission of 1896, whose attention was directed from the
first to an epidemic of casualties that had made its appear-
ance in the hot summer, 1895—1896. Analysis of the data
clearly showed that spontaneous fires were associated
with high maximum temperatures, and special experi-
ments on a large heap of slack showed that at a
depth of from 3—4 in. from the surface coal exposed to
the sun reached a temperature from 20° to 40° F. beyond
the recorded maximum shade temperature. From 1892
to 1896 inclusive, the lowest maximum shade temperature
recorded during the loading of a cargo which afterwards
fired was 63° F., and the highest 103° F., the average being
over 90° F. That such a seasonal variation in the number
of casualties should occur under the sunny sky of Newcastle,
N.S.W., will surprise no one—but I had not expected
that the same thing would have been noticeable under
the overcast climate of England. I was, however, anxious
to examine this point, and was fortunate enough to find,
in the report of the R.C., 1876, a most magnificent set of
data, prepared for the use of the Commission by Mr.
R. Cooper Rundell. These unrivalled data, referring to
no less than 4898 shipments and 102 casualties, are
tabulated below, and from them the curve of percentage
casualties which is treated as a seasonal phenomenon is
plotted against the mean temperature curve—not for the
particular years involved, but for the period 1841—1905,
as printed in Whitaker's Almanack. Mr. Rundell's data
refer to all fires in coal cargoes, and no doubt a few of
those were not strictly spontaneous. Consequently it did
not seem worth while to go beyond the long period tem-
perature curve—especially as the data refer to all United
Kingdom ports.

FIG. 10.

Casualties from Fire or Heating for all Ports of the United Kingdom, and for each month of the year, expressed as
percentages of shipments of 500 tons of coal and upwards on voyages across the equator and through the Suez
Canal, prepared from R. Cooper Rundell's data presented to the Royal Commission of 1876.

It has been a great pleasure to me to discover this important relation from the study of data buried for over years, and to reflect that Mr. Cooper Rundell's laborious work has at last borne fruit. An important fact has thus been established, and the pyrites theory, also, is shown by the data alone to have no practical bearing on the spontaneous heating of coal on board ship.

5. Breackage of coal during shipment has long been recognised as a possible contributing factor to spontaneous combustion. No special comment need be made in view of the account given above of the theory of heating—except that the general opinion appears to be justified. The Commission of 1876 devoted much time and trouble to the examination of the system of loading in vogue in England at the time, but could only point out that all these systems, whether tips, cranes or spouts, gave rise to breackage. Since that time the Lewis and Hunter system of loading has been established at Cardiff, whereby an immense improvement in regard to prevention of breackage has been brought about. In other systems a coal is allowed to fall at least from the combings of the hatch, but in the Lewis and Hunter system the coal is first transferred from the truck to a loading box and this box is then lowered down the hatchway till it reaches the bottom of the ship, or top of the cargo, when the coal is put out practically without breackage. I examined this system in 1898, and in my ignorance had expected to find that it would have been used primarily in loading sailing vessels to diminish the risk of spontaneous heating by minimising the cause. It turned out, however, that the advantages of relatively unbroken coal had been so appreciated by the consignees that the Lewis and Hunter cranes were kept fully occupied in supplying the more important customers, *i.e.*, the steamship companies, who port coal largely for re-coaling purposes, and the unfortunate sailing ships were at that time (however it may be now) still loaded from old-fashioned appliances. The cost of installation of the Lewis and Hunter system is, however necessarily large, and I thought at one time that the same result might be achieved by ordinary cranes lifting railway trucks and lowering them through the hatchways before discharging. It appears, however, that large hatchways are not tolerated at Lloyd's on account of the structural weakening of the ship, which, in the absence of special precautions, would no doubt result. It should not be beyond the resources of engineering to get over this difficulty, however—the trouble would be in the interregnum while ships with small hatchways still had to be loaded, and the proposal must, I suppose, be regarded as an unpractical idea.

It is worth noting that the effect of breackage during

loading may be more serious with some coals than with others. Thus a witness before the 1876 Commission mentioned that some Welsh coals when broken by a fall fell into more or less cubical fragments, while other kinds of coal broke irregularly and made more dust. If these coals had the same inflammability to start with, the second kind would naturally be more dangerous than the first.

No account of spontaneous heating of coal on board ship would be complete without a reference to the subject of gas explosions. An explosion is often a consequence of spontaneous heating of a cargo of coal, and is sometimes the first indication a captain gets that his cargo has heated. The cause, of course, is the low temperature distillation going on, at, and around, the centre of heating, and the gas generated is usually almost or quite colourless. In a case of which I have had personal experience the scent of the gas was between that of benzene and paraffin oil—an odour which is easily recognisable once it has been smelt—it is not at all like that of town gas. As heating progresses the distillation products become visible, and in this case an actual outbreak of fire can only be a matter of a few hours. Carbon monoxide is probably always a constituent of the gas evolved from the hot coal and cases of poisoning have been reported, but none have come under my personal notice—at least in so far as coal cargoes are concerned. The gases coming from a spontaneous fire in a mine examined by me showed 0.2 per cent. CO—a quantity which could not be breathed with impunity for more than a short time, say, half an hour. The danger of explosion has in the past been aggravated by the habit of battening down when a smell of gas is first perceived, in the hope—I believe almost if not quite universally illusory—of cutting off all access of air to the cargo. Having in view the fact that the explosion of weak mixtures probably gives rise to pressures of less than 100 lb. sq. in. (Mond gas uncompresssed is said to have a maximum explosion pressure of 60–70 lb. per sq. in.), it is wonderful what destruction can be brought about on ship board by such explosions. On the whole, if the cargo heats, I think it is better to be sure that the surface ventilation is adequate by removing the hatches, than to try to keep all air from the coal, though, of course, if the latter could really be done the fire would eventually go out, as in Fayol's experiment with the bell.

In addition to explosions from gases due to heating of the cargo, coal shippers have had much trouble from explosions occurring within a few days of the loading of the cargo. In these cases the cause is to be found in the spontaneous evolution of Marsh gas by newly mined coal. Two such explosions in Sydney Harbour came under

my notice, and in one case I was able to visit the ship within a few hours of the disaster. The effects were exactly such as might have been expected, the deck had been burst upwards and the deck fittings destroyed—the ship was in fact completely disabled. An efficient system of ventilation of the space between the cargo and the deck, by windsails if necessary, will of course entirely get over the risk of explosion from newly-won coal.

Through the kindness of Mr. S. Bullock, Superintendent for Wrecks at the Board of Trade, I am able to bring the statistics of the subject of casualties through spontaneous heating up to date in the following tabular statement, which I owe entirely to Mr. Bullock. I should have been glad to have been able to sift the data so as to ascertain whether there has really been a diminution in the percentage number of spontaneous fires on sailing ships in recent years, or whether, as I suspect, the apparent reduction is largely an expression of the increased use of steamers as colliers. The steamer, of course, owes its comparative immunity to the fact that it generally completes its voyage within the incubation period of a spontaneous fire.

Prevention of spontaneous fires.

The Second New South Wales Commission made the following recommendation:—"Having in view the fact that cases of spontaneous heating invariably occur in the heap of small coal under the hatchways, and in the light of the foregoing conclusive result, we recommend that where large ships are being loaded during warm weather (say, when the temperature of the air is 90° F. or over) a hose should be played down the hatchway so as to wet, at all events, the coal which collects at that spot."

This recommendation was made with full knowledge of the theory of the matter and with the results of a large, costly and conclusive experiment before the Commissioners; and everything goes to show that a cargo thus treated would be absolutely safe, if not for ever, still for a much longer period than is occupied by any ordinary voyage. In the year 1900 I ascertained that at Cardiff it is not unusual to spray the coal during loading, in exceptionally dry weather, to lay the dust a little—a system good so far as it goes, but one which gives no security that the dangerous part of the cargo under the hatches is really wet enough. Mr. Bullock's figures clearly show that from one cause or another spontaneous fires on board ship are now much less frequent than they used to be, but I consider that with our present knowledge of the subject, there should be no spontaneous heating of cargoes at all. The means to be adopted are simple. In the first place if the weather is cold during the time the coal is in transit, and being loaded, no special precautions appear to be necessary except in regard to surface ventilation. If the weather is warm, and particularly if it is sunny, and if the coal has been lying in trucks exposed to the sun, the heap of small coal and dust under the hatchways should be attended to. One way would be to dig out the heap under the hatchways and distribute the coal over the rest of the cargo, replacing it by larger coal, as has occasionally been done. The objection to this would be the cost. From measurement of some drawings I estimate that about one-fifteenth of the cargo might have to be retrimmed. If we consider a cargo of 2000 tons, this means the restowing of about 130 tons. This could not cost more than about 6d. per ton for labour, or £3 5s., to which would be added possible charges for demurrage—which I am not in a position to estimate. Instead of delaying a ship under the cranes or tips (which would have the advantage that when the hatches were dug out the holes could be filled in direct from the loading appliances), it might be preferred to do the filling in from the rest of the cargo, though this could hardly be done conveniently if the ship was well loaded. In this case the labour charge would be higher, perhaps double the figure given above.

A more certain and less laborious precaution would be the adoption of the recommendation of the second N.S.W. Commission to wet the heap of fines under the hatchway. I have shown that such a mixture is thoroughly wetted

if it carries 10 per cent. of water. The coal probably would carry 2 or 3 per cent. of water on an average in any case, so we may reckon that about one-fifteenth of the cargo would have to carry 8 per cent. excess water. This is an increase of weight of about $\frac{1}{10}$ per cent. calculated on the whole cargo, and I believe the estimate to be above rather than under the mark. As to the means of carrying out the distribution of water, it would be a simple matter to arrange a Koerting's spray nozzle to play down the hatchway during the loading, and the delivery of water could be easily adjusted till the coal was observed to be thoroughly wetted where it needed to be wet. A still simpler plan would be to finish the trimming by leaving a depression in the surface of the cargo under the hatchway and pouring in water—salt or fresh—till the calculated amount, up to $\frac{1}{10}$ per cent. of the weight of the cargo but possibly only $\frac{1}{20}$ per cent., had been added and allowed to soak down.

I regret that I have only estimates to offer instead of actual measurements of the water required, but I have had no opportunity of late years of experimenting on whole cargoes. Anyone wishing to complete the subject and in a position to measure the water required would be doing a good service by publishing the result of a few experiments. I hope to live long enough to see the occurrence of a spontaneous fire at sea regarded rather as the result of culpable negligence than as the kind of misfortune defined in bills of lading as "The act of God."

DISCUSSION.

The CHAIRMAN said that the subject-matter of the paper was exceedingly important regarded from either the humanitarian, economical, or scientific points of view. The author's references to coal matters having relation to the shipping trade were most interesting, and one would like to know what were his experiences in coal mines. In the Chairman's opinion, sulphur did not have much to do with the spontaneous combustion of coal and coal which readily fired was thick coal which contained less sulphur. Spontaneous combustion was said to be more usual in mines in which the coal was ground exceedingly fine. On that account it was more readily oxidised, and spontaneous combustion soon occurred. He had seen it recorded that ferrous sulphate was calculated to produce combustion by catalytic action.

Mr. A. E. TUCKER pointed out that in some coal sulphur did not exist entirely as pyrites, and he had known a case of coal, which came from China, containing 6 per cent. of sulphur which was entirely in the uncombined form. Whether the question of the state of the combination of sulphur in coal affected the general point of spontaneity of combustion was a matter upon which he would like some expression. If, as was suggested, the liability to combustion was due to the high percentage of hydrogen present it occurred to him that the presence of sulphur existing in other forms of pyrites might bring about the same result. The matter of spontaneous combustion had been brought sadly home to them in the Birkenhead district in connection with the Hamstead Colliery, where, by reason of the peculiarly geological formation, the seams of coal were particularly liable to slip, with the accompanying generation of heat.

Dr. R. S. MORRELL said a question which was of interest to him was deterioration of coal when it was stored. What were the best conditions for the preservation of coal, in respect of the retention of its calorific value under varying conditions of temperature and moisture?

Mr. THRELFALL, in reply, said the best method was to keep the coal in such a condition that it would not heat, and that was achieved by keeping it at a minimum thickness which could be determined by trials. In Fayol's coal it was necessary to have it less than 4 in deep, while in Australia stacks twelve ft. high, of Newcastle coal, rarely heated; but stacks of 20 ft. always heated. So much depended, of course, upon the climate. With regard to the question of sulphur, that had been a bogey for many years, and he wanted to lay it that evening. If they would reflect on the fact that in ships no fire was ever started except under the hatchway, they would see that the presence of pyrites did not throw any light on

question of the cause of the fire. If the fire took place anywhere else in the ship there might be a question as to the possibility of sulphur becoming separated from the pyrites, the sulphur did separate, but not till the pyrites was heated to 400° C., under which temperature the coal yielded no assistance whatever. On the subject of the spontaneous heating of coal in mines, he would be glad to receive further information from anybody who had such knowledge at first hand. He had investigated several cases, but nothing compared with the number of fires in mines, and in those cases the fires in the mines had all taken place in dry places. He knew of no fires having started in a damp place in a mine. He should be glad to hear from you.

Mr. TUCKER asked whether the author had known of any cases of spontaneous combustion in ships arising from the use of patent fuel, and whether the conditions of manufacture of patent fuel prevented such combustion?

Mr. JOHNS said with regard to coal used in the manufacture of gas, his experience was that the value was increased if the coal was stored for any length of time. In gasworks it was necessary to store large quantities of coal in order to tide over periods of strikes or shortages of supply. He instanced a case in which a quantity of coal, having been stocked for 2 or 3 years, gave a return of 10,000 c. ft. per ton instead of 10,200 c. ft. The calorific value was also considerably reduced. Gas engineers held the view that the longer coal was stored the less quantity of gas was to be expected from it. The heating value of coal was similarly affected.

Mr. H. L. HEATHCOTE asked what bearing the temperature of the air at the time the coal was loaded had on the frequency of the fires. He would like to know whether humidity had any effect.

Mr. THREEFALL, further replying, said it made little difference to the coal whether it was stored 3 ft. deep in this country. But at 10 ft. it was rather a question. He felt that 10 ft. would be about the limit coal would be stored without deterioration. The varying experience may have been due to the circumstance that different sorts of coal were stored. There were many varieties of coal,

and the difference between some of them was very pronounced, so that without further explanation he saw no reason for thinking that the experiences mentioned were contradictory. He did not think he had ever come across an instance of the firing of a cargo of patent fuel. The spontaneous heating of patent fuel could not be a very common thing if it happened at all. He did not think that the percentage of water composition of the coal loaded into a ship would be materially affected by the humidity of the air at the time the coal was loaded. In dry weather it might be a little bit dryer, and in damp weather a little bit damper, but the main cause of difference in the quantity of water would depend upon the amount of water naturally existing in the coal in the mine and not in the air. The rainfall while the coal is in transit must also be considered. Moreover Richters had shown that it made no difference whether the air was dry or moist. Fayol had made the same experiment, and personally, in view of these experiments, he had not thought it worth while to consider the effect of humidity in producing spontaneous fire; nor did he think it had any kind of comparison with the effect—the greater effect—exercised by the water which was normally present in the coal as it was raised from the mine, and on the rain which fell upon it on its way to the ship.

MR. E. GRANT HOOPER IN THE CHAIR.

A NEW REFRACTOMETER.

BY DR. J. LEWKOWITSCH.

The construction of the new refractometer (shown in Fig.) made by Hans Heele, Berlin,* is based on the

* The English representative is Mr. P. Heele, 34, Drayton Gardens, West Ealing, W.

Kohlransch-Abbe method of determining the angle at which the limiting ray, entering the object under observation at grazing incidence, emerges from a cylinder quadrant made of French flint glass of high refracting power. The detailed directions for the construction of the optical portions of the instrument were furnished by Professor Harland of Brussels. It will be noted that the refractometer resembles the Pulfrich refractometer (See Chemical Technology and Analysis of Oils, Fats and Waxes, 4th Ed., Vol. I., p. 253), but it differs from it in that essential point, that instead of the rectangular prism of the Pulfrich instrument, a cylinder quadrant is employed.

The object to be examined is placed on the polished horizontal surface of the quadrant. As will be seen from the illustration, the light falls into the substance under grazing incidence, and the limiting ray, after emerging from the cylinder quadrant, passes through a concave cylinder segment (made of the same highly refractive glass as the cylinder quadrant, and of the same radius) in the telescope and thence into the eye of the observer. The angle is read off an arc which is divided into one-quarter degrees (15 minutes); by using the "vernier," single minutes can be read off without any difficulty. In order to obtain still greater accuracy, a micrometer screw is provided, the drum of which is divided into 50 divisions. As one total revolution of the drum corresponds to 15' or 900", one division corresponds to 18"; this forms the limit of accuracy obtainable with this apparatus. From the observed angle, i , and the known refractive index, N , of the cylinder quadrant, the refractive index, n , of the substance under observation is found with the aid of the formula, $n = N \cdot \sin i$.

In order to obviate calculations, there is furnished together with the apparatus a table in which the refractive indices, n , are calculated out from 10 to 10 minutes for all the angles between 34° 44' 30" and 87°, for the sodium line D. For any other wave length the refractive index must be calculated; for this purpose the values of N for the rays A', C, D, F, G' are given in the table. Thus all refractive indices between 1 and 1.733 can be observed. (For higher refractions it would, of course, be necessary to use a cylinder quadrant, etc., of still higher refractive power). The instrument is so adjusted that the angle for air is 34° 44' 30". This is of great importance, inasmuch as it enables the operator to determine the zero point, as it were, of the instrument at any time.

To observe the refractive index, a sodium lamp or any other monochromatic light is thrown from a distance of 12 to 16 inches through the rectangular prism on to the object under observation. By turning the rectangular prism downwards and sparking the hydrogen tube provided (see Fig.), the refraction for the hydrogen line can be observed, and by thus changing the source of light the dispersion can be measured rapidly, as it is only necessary to turn the micrometer drum, until the dividing line between the dark and the illuminated fields passes again through the centre of the spider web in the telescope.

This dividing line is more sharply defined and is less curved than is the case in other instruments. Therefore the angle can be adjusted with greater accuracy than is the case in similar instruments. This, together with the wide range of angles than can be observed, and coupled with the fact, already mentioned above, that the zero can be checked without any difficulty in the shortest time, constitutes the chief features of the new instrument.

Inasmuch as the refractive indices of solid, liquid, and gaseous substances can be determined with this instrument it may be termed a universal refractometer.

In order to make observations at any desired temperature the quadrant is surrounded with a water jacket. Solid substances are examined by placing the instrument on the horizontal face of the cylinder quadrant. For the observation of liquid substances, at first an open trough (open both at top and bottom) was provided. This trough was to be fitted to the horizontal face of the cylinder of the quadrant by means of wool wax and the liquid was then poured into the trough. The liquid could be brought to the desired temperature by means of a heating apparatus, G, similar to the one supplied with the Pulfrich refractometer (cp. Chemical Technology and Analysis of Oils, Fats, and Waxes, 4th Ed., Vol. I., p. 253). The fixing of the trough, however, did not prove satisfactory in my own practice, and at my suggestion the construction of the trough has been altered in the following manner: The bottom edges of the four vertical side plates of the trough are bevelled, so that the loose bottom plate, which is also bevelled off at its edges, closes the trough tightly, especially if a slight pressure is applied by means of clips fixed on the jacket of the trough. It is, of course, necessary to place between the bottom of the trough and the horizontal face of the cylinder quadrant a liquid of a higher refracting power than that under observation. For liquids, a differential trough (suggested many years ago by Ostwald) may be used, so that two liquids can be observed simultaneously and the differences of the refractive and dispersive powers can be measured directly.

Of late years the butyro-refractometer has gained ground in chemical laboratories for the examination of oils and fats, and a comparison between the butyro-refractometer and the new refractometer will naturally suggest itself. When instituting such a comparison, must not be forgotten that the present instrument is a universal one, whereas the butyro-refractometer is specially constructed for the examination of butter fat. Hence in the latter case the critical line of total reflection is achromatised (cp. *Ibid.*, Vol. I., p. 250), and the line dividing the dark and illuminated fields appears colourless. If other fats or oils are observed in the butyro-refractometer, the dividing line is always coloured, whereby the exact reading becomes somewhat uncertain in so far that a lesser refraction than one "degree" can only be estimated. Even after applying the micrometer suggested by F. Löwe (*Ibid.*, p. 250) the accuracy cannot be extended to more than several tenths of a "degree". The following table will show that with the new refractometer

Substance.	New refractometer.		Butyro-refractometer.	
	Medium used.	For D line.	"Degrees."	Calculated.
Water*	Wintergreen oil 40°	34' = 1.33568	—	—
Tung oil*	" 50°	59' = 1.51943	—	—
Sofa oil	" 57°	31' = 1.48025	82°	1.4794
Malze oil	" 57°	15' = 1.47683	76°	1.47590
Cottonseed oil	" 57°	20' = 1.47721	76°	1.47590
Rape oil	" 57°	19' = 1.47695	76°	1.47590
Arachis oil	" 57°	4' = 1.47278	70°	1.4723
Olive oil	" 57°	4' = 1.47278	70°	1.4723
Castor oil	" 57°	38' = 1.48215	84°	1.4807
Neats foot oil	" 57°	1' = 1.47195	67°	1.4705
Cod liver oil	" 57°	38' = 1.48215	84°	1.4807
Whale oil	" 57°	23' = 1.47804	77°	1.4795
Thyme oil*	" 58°	45' = 1.50017	—	—
Wintergreen oil*	Carbon bisulphide 61°	15' = 1.53846	—	—
Rosin oil* (containing rosin acids)	" 61°	8' = 1.53675	—	—
Rosin oil* (free from rosin acids)	" 61°	50' = 1.54696	—	—

* In this case the butyro-refractometer is useless.

ter (which shares of course this advantage with other testing refractometers) differences are easily ascertained which would escape when using a butyro-refractometer of the old construction (without a micrometer), as was the case for the observations given below. It should further be pointed out that duplicate observations with the new refractometer agree down to a minute. Moreover, it should be borne in mind that even in fat and oil analysis the range of the butyro-refractometer is restricted, for in oil and tung oil fall outside its limits. Therefore, for refractometers must be used side by side with the butyro-refractometer, and for such purposes the present refractometer can be recommended.

The observations in the new instrument require, of course, more substance than with the butyro-refractometer and its congeners. As regards rapidity of work may, however, be stated that by using a number of enough the number of observations that can be made in a given time can also be very large. I append a list of comparative observations made.

The last two observations would suggest the application of the refractometer for the examination of the different commercial brands of rosin (colophony) in the solid state.

DISCUSSION.

The CHAIRMAN enquired the cost of this instrument, and appeared to have considerable resemblance to the Pulfrich refractometer, and he desired to ask what were the special advantages possessed by this instrument over the Pulfrich. Was there greater convenience of reading? Everyone who had experience of the ordinary butyro-refractometer would agree that when used for other substances than butter fat the readings are not quite sharp. The new instrument he gathered is of more general application, and gave closer readings. Mr. E. R. BOLTON thought that the butyro-refractometer had hardly had full justice done to it. The divisions of the scale were now divided into tenths by a micrometer screw. The line could be made clear and sharp using sodium light and also reducing the aperture of the bottom of the instrument by inserting a strip of card. Under those conditions there was no difficulty in obtaining any number of consecutive readings to e-tenth.

Dr. LEWKOWITSCH, in reply, said the disadvantage having to use a larger quantity of liquid than in the butyro-refractometer was obvious; but at a very little additional expense a number of the glass troughs might be obtained; in the Fery refractometer the quantity of liquid used was still greater, and the washing out of the trough caused much more inconvenience. He held brief for this instrument, but simply brought it forward as a new apparatus, offering certain advantages. The cost was about £30. The principal advantage over the Pulfrich instrument was that the dividing-line could be more easily fixed. With regard to the micrometer screw of the butyro-refractometer, he would defy anybody to read accurately tenths of degrees. Of course, the butyro-refractometer was a very excellent instrument for sorting commercial butters; in fact, it was used for that purpose by German police officers. And could be used with ordinary daylight, as well as with sodium light, but if it were used for any other oil or liquid they had to deal with a different dispersion, and the difficulty caused by a coloured line came in. This was the fault of the instrument, but the fault of the chemist who tried to get more out of it than it was designed to perform. By using a sodium light as Mr. Bolton did other complication was introduced. And if one went the trouble of using a sodium light one did away with the one great advantage of the butyro-refractometer when applied to oils and fats other than butter. He would like to repeat that the butyro-refractometer was not comparable with the new apparatus, which was a universal instrument applicable to solids, liquids, and gases.

A paper entitled "Vulcanisation Tests on Plantation Rubbers," by Messrs. Clayton Peadle and Henry P. Evans; M.A., Ph.D., was also read and discussed.

Scottish Section.

THE LIME IN BASIC SLAG.

BY JAMES HENDRICK, B.Sc., F.I.C.

Basic slag is now one of the most important of phosphatic manures, the annual consumption of which is measured in millions of tons. Its particular value as a manure is related to the fact that, although it contains a large proportion of lime and is alkaline in reaction, its phosphate is easily soluble in weak reagents and is therefore readily available to plants. Certain of the natural mineral phosphates, such as the largely used phosphates of Algiers and Tunis, also contain large proportions of lime, proportions far more than sufficient to fully combine with all the phosphate present, but their phosphate is not nearly so soluble in weak reagents and is not so available to plants. The chemical condition in which the phosphate and lime exist in basic slag is therefore a matter of great practical importance, and has received much attention from investigators.

It is commonly stated that basic slag contains a considerable proportion of "free lime." This statement is reproduced in well-known works on manures and on agriculture, and the "free" lime in slag is constantly referred to in writings on manures and manuring. For instance, the well-known manual on Manures and Manuring, by the late Dr. C. M. Aikman, states, p. 404, the free lime of average slag at 15 per cent.; and the latest edition of that standard work, "Stephen's Book of the Farm," states, Vol. I., p. 360 (1908), that one-third to one-half of the total lime in basic slag is in the caustic state, and again, at p. 500, that basic slag contains "a considerable quantity of caustic or free lime." A similar statement is contained in a recently issued leaflet of the Board of Agriculture and Fisheries, No. 170. The origin of these statements is to be found in the original papers of certain investigators who deal with the composition of slag and the state of the lime and phosphate in it. Thus, in a paper by Otto* the free lime (CaO) is stated as 11.0 per cent., and in a paper by Jensch† at 16.01 per cent. In both these cases the free lime was determined by means of a sugar solution.

G. Paturel‡ determined the free lime in a number of slags of French origin, and found from 2.55 to 21.43 per cent. In this case the determinations appear to have been made by means of a solution of ammonium chloride, which he says would not act on either calcium silicate or basic calcium phosphate. I have not been able to discover the record of any British determinations of the free lime in slag; though the presence of a considerable percentage of free lime is often assumed in British writings.§

Some time ago, I made some determinations of the free lime in slag by the method of solution with sugar, which I use for determining the free lime in burnt limes. In this method the lime, or substance containing lime, is shaken with a 10 per cent. sugar solution in a mechanical shaker for four hours, and an aliquot part of the solution titrated with standard hydrochloric acid.¶ To my surprise the amount of lime found was under 1 per cent. Similar amounts were found in several samples of slag. Thinking that possibly the free lime had been turned to carbonate by exposure, the carbon dioxide in some of the samples was determined, but the quantity found was so small as not to account for the absence of free lime in the samples, assuming they had originally contained 10 per cent. or over. The amount of carbon dioxide found in different samples varied from nothing to 1.5 per cent. The free lime was therefore determined directly in a large number of samples. Many of these were commercial samples of uncertain age, but a number were quite fresh samples specially obtained from the makers, and a number were samples of known origin

* Chem. Zeit., 1887, 255, and Zeits. f. Chem. Industrie, I., 257.

‡ Ann. Agronomiques, 1896, 22, 449.

§ Hughes (this J., 1901, 327) considers that basic slag does not contain more than 2 or 3 per cent. of caustic lime.

¶ Hendrick, Analyst, 1907, 32, p. 320.

and age. The average for ten commercial samples of unknown age was 0.99 per cent., and they varied from 0.57 to 1.57 per cent. All of these determinations were made by the sugar method. One sample which was known to be over two years old gave 1.12 per cent., another which was known to be only a few months old gave 0.84, and one which was known to have been ground a few weeks before being tested gave 1.26 per cent.

Several samples were tested for me by the sugar method, on the day they were ground by Mr. P. A. Keller, then chemist to Messrs. J. and J. Cunningham, Leith. These gave from 1.20 to 1.43 per cent. of free lime. All these were slags containing from 16 to 18 per cent. of phosphate estimated as tricalcium phosphate.

After these preliminary tests seven samples were obtained, and the free lime in them was determined in my laboratory by three different methods. The results are given in Table I. Samples Nos. 3 and 4 are Middlesburgh slags, and No. 5 is a South Bank slag. All these were obtained through the kindness of The Chemical Works, late H. and E. Albert, London. No. 1 was obtained from Messrs. J. and J. Cunningham, Ltd., Leith; and No. 2 is a Glangarnock slag obtained from Messrs. Alex. Cross and Sons, Ltd., Glasgow.

These five samples were all freshly ground. In the case of the samples from Middlesburgh, not only were the slags freshly ground, but they were ground from freshly made slag. The samples were preserved from free contact with the air in air-tight bottles until they were tested. Nos. 6 and 7 were commercial samples of unknown age.

The free lime was determined (a) by the sugar method already mentioned, (b) by extraction with distilled water, and (c) by extraction with ammonium chloride solution. The water extraction was conducted by shaking 5 grms. of slag with 500 c.c. of recently boiled and cooled distilled water for 4 hours in a mechanical shaker. An aliquot part of the solution was then titrated with decinormal hydrochloric acid. The amount of water used was sufficient to have dissolved all the free lime present even if it had amounted to over 10 per cent.

In the ammonium chloride method 4 grms. of slag were shaken with 200 c.c. of recently-boiled and cooled distilled water containing 1 gm. of ammonium chloride in solution. Each sample was thoroughly shaken at intervals for several hours. After the solutions had settled 50 c.c. was decanted off and titrated with decinormal hydrochloric acid.

TABLE I.
Free Lime.

No. of Sample.	Sugar Method.	Water Method.	Ammonium Chloride Method.
	per cent.	per cent.	per cent.
1.....	0.84	0.66	5.2
2.....	2.30	1.58	5.13
3.....	3.08	2.07	3.92
4.....	2.03	1.28	2.99
5.....	1.20	0.65	3.52
6.....	1.60	0.63	3.15
7.....	1.44	0.48	1.67

The table shows that extraction with water gives the lowest results, and the ammonium chloride extraction the highest results in every case. It is probable that the water extraction gives results which are below the truth, for when the shaking was continued for a longer period higher results were obtained, but in no case, even when the shaking was continued for two or three days, was the result by water extraction quite as high as that obtained by the sugar method.

As a sugar solution readily dissolves free lime, the results by this method are not below the truth. They may be a little above it, for certain compounds may break up and give up free lime on shaking with sugar.

On the other hand, the results with ammonium chloride are almost certainly above the truth. This question is discussed later.

The above results show that the percentages of free or caustic lime commonly stated to be present in basic slags are not found in the slags at present on the British market. As a rule, the amount of free lime present is under 2 per cent., and it is often under 1 per cent. It is probable the different results obtained by earlier investigators were due to a greater excess of lime being used formerly in the preparation of basic steel. There has been a considerable alteration, I understand, in the methods of preparing basic steel, and its by-product basic slag, during the past 20 years. These alterations are reflected in the composition of basic slag, though writers on manures do not appear to have taken note of them.

Lime available as a base in basic slag.—While the amount of free lime in basic slag is thus shown to be very small it will be obvious to anyone who has worked much with slag that the proportion of lime present in form in which it is available as a base, and can neutralise acid when brought in contact with them, must be considerable. Thus, if we mix slag and superphosphate together the amount of reversion of soluble phosphate to the insoluble state which takes place cannot be accounted for by the small amount of free lime present. It is also obvious that in fresh slag the lime cannot be present as carbonate, and as shown above, even in ordinary commercial slag which have been exposed to a considerable extent, the carbonate present is so small in amount as to be unimportant.

From an agricultural point of view it is the lime which is available as a base, and not merely the free or caustic lime, which is important. Lime which is so loosely combined as to be capable of neutralising acidity and acting as a base during nitrification is what is desired in the soil. Free alkali is not desired in the soil, but lime in the form of carbonate, in which it is not free and does not render the soil strongly alkaline, yet is available to neutralise acidity in the soil, is what is required. In basic slag there is a considerable percentage of lime in forms in which it is available as a base.

When ammonium sulphate in the soil undergoes nitrification, a base is required to neutralise the sulphuric and nitric acids formed. This suggested that the amount of lime available as a base for use in the soil might be estimated in the case of basic slag by distilling the slag with an excess of ammonium sulphate and measuring the ammonia liberated. Some preliminary experiments showed that the ammonia obtained in this way was equivalent to many times the amount of free lime found in the slag. It was also found that the result varied considerably with the conditions of the experiments. The seven slag already referred to were therefore tested under exactly similar conditions. Both ammonium sulphate and ammonium chloride were used.

A solution containing 1 gm. of ammonium sulphate or containing ammonium chloride equivalent in ammonia to 1 gm. of ammonium sulphate, 0.811 gm., was added to 1 gm. of slag, and slowly distilled into standard acid for 1½ hours. The bulk of the solution at the start was in every case 200 c.c. The amount of ammonia found was calculated into percentage of lime in the slag. 100 c.c. more water was then added to the solution at the distillation continued into a fresh portion of standard acid for another hour, and the equivalent in lime again determined. This was repeated three times more, till the total time of distillation was 5½ hours. In every case more ammonia was obtained, but the amount began gradually less, till at the 5th distillation it was very small.

In Table II. the analyses of the seven samples of slag are given. The citric soluble phosphate was determined by the British official method. [The Fertiliser and Feeding Stuffs (Methods of Analyses) Regulation 1908.]

The citric soluble lime was determined in the same solution as the citric soluble phosphate. The lime available as a base was determined by distillation with ammonium sulphate for 5½ hours. Table III. gives the determinations of the lime available as a base by distillation both for 1½ and for 5½ hours and with both ammonium sulphate and ammonium chloride.

TABLE II.
Table of Analysis.

	No. of Sample.						
	1	2	3	4	5	6	7
total phosphate ($\text{Ca}_3\text{P}_2\text{O}_8$)	per cent. 33.79	per cent. 31.50	per cent. 32.37	per cent. 32.73	per cent. 29.94	per cent. 27.70	per cent. 35.40
citric soluble phosphate ($\text{Ca}_3\text{P}_2\text{O}_8$)	15.50	30.60	30.04	25.34	27.50	21.40	33.60
total lime	48.60	45.30	43.60	41.24	45.10	35.30	39.70
citric soluble lime	31.10	34.50	31.90	27.80	40.00	29.00	34.80
free lime (Sugar method)	0.84	2.30	3.08	2.03	1.20	1.60	1.44
lime available as a base	28.30	24.40	19.31	15.23	24.05	22.30	13.60
calcia	17.56	13.30	12.65	15.40	16.90	30.80	16.00

Table II. shows that sample No. 1. was abnormal. It contained a very low percentage of citric soluble phosphate, although the total lime and the lime available as a base were higher than in any other sample. The table also shows that the slags varied greatly in the percentage of silica which they contained, and that there is no definite relation to the citric solubility of the phosphate. The free lime and the lime available as a base do not appear to bear any definite relation to one another or to the citric solubility.

that it readily acts as a base and liberates ammonia from its salts, and another considerable, though generally smaller, portion which is more slowly liberated, but which gradually becomes available as a base under the conditions of the experiment. Even after 5½ hours' distillation ammonia was still being slowly liberated in every case, so that the limit of the lime capable of liberating ammonia from ammonium sulphate or ammonium chloride had in no case been reached.

It is impossible to say how much of this lime would

Table III. shows that in practically every case more ammonia was obtained by distilling with ammonium sulphate than by distilling with ammonium chloride. This is probably because the lime is largely present as silicates, and sulphuric acid decomposes silicates more effectively than hydrochloric acid.

With the exception of Sample 4, from two-thirds to three-fourths of the ammonia was given off in the first distillation, the remainder was given off slowly in gradually increasing quantities. This is illustrated in Table IV., which shows the percentage of lime equivalent to the ammonia given off at each stage of the distillation with ammonium sulphate in the cases of Samples 1, 2, 4 and 6. Similar results were obtained in all the other cases both with ammonium sulphate and ammonium chloride.

TABLE IV.

Lime available as a base.

Lime equivalent of the ammonia liberated at different stages of the distillation with ammonium sulphate.

Evidently, then, in addition to any free lime present, there is a large amount of lime which is so loosely combined

be capable of acting as a base under the very different conditions which prevail in the soil. Table I. shows how much was capable of liberating ammonia when merely shaken with a cold solution of ammonium chloride; and that this amount was generally considerably in excess of the free lime found by extraction with sugar solution.

It was also found that when the solution of ammonium chloride with which the lime was first shaken was removed and the residue of the slag washed by decantation, more ammonia was liberated in the cold when a new solution of ammonium chloride was added and the slag residue shaken with it. This was tried with the three samples, Nos. 4, 5 and 7. These after washing were again treated exactly as before with 200 c.c. of water containing 1 gm. of ammonium chloride. (See Table I.) On titration the solutions showed alkalinity corresponding to the following percentages of lime:—No. 4, 0.62 per cent., No. 5, 1.20 per cent., and No. 7, 0.81 per cent. In the case of No. 7, the alkalinity is about half that obtained in the first treatment (Table I.).

In all the above tables it has been assumed that lime is the only base present which liberates ammonia. It is probable that the liberation of ammonia is partly due to the action of other bases present in the slag. Basic slag contains a little magnesia and much ferrous and ferric iron, and these will not be without action.

The amount of available base in these slags was calculated in another way. The 2 per cent. citric acid solution which was used in the determination of the citric solubility of the slag was partly neutralised by the slag. The residual acidity was determined by titrating with standard soda, and the equivalent of the portion neutralised by the slag was calculated into percentage of lime. The figures obtained in this way have already been given in Table III. They are much greater than those obtained in any other way. This is probably due to the amount of citric acid which was neutralised by iron and bases other than lime.

Without entering into the long-continued controversy as to the forms of combination in which the citric soluble phosphate in slag exists, we may assume that part of it, at any rate, exists as the tetra-calcium phosphate, $\text{Ca}_4\text{P}_2\text{O}_8 \cdot \text{CaO}$. This salt is capable in presence of dilute acids of breaking up and liberating lime which acts as a base. There is reason for believing that each molecule of $\text{Ca}_4\text{P}_2\text{O}_8 \cdot \text{CaO}$ contains two molecules of lime in a lower state of combination than the others, hence when it breaks up with weak acids it forms di-calcium phosphate and liberates two molecules of lime.* Part of the lime capable of liberating ammonia from its salts is probably obtained in this way.

considerable proportion of it must be derived in most cases from other compounds. It is probable that this lime, most of which is comparatively slowly liberated, is contained in silicates. The exact proportion of the lime capable of acting as a base which is derived from silicates there is no ready means of estimating.

Table V. also shows (c) the citric soluble lime. This was the total lime dissolved on treating the slag sample with 2 per cent. citric acid by the official method for the estimation of phosphate. It was estimated by precipitation as oxalate. It will be seen that this citric soluble lime bears no relation even approximately to the lime

TABLE V.

	No. of Sample.						
	1	2	3	4	5	6	7
(a) Lime from tetra-calcium phosphate.....	per cent. 5.00	per cent. 11.04	per cent. 10.84	per cent. 9.14	per cent. 9.94	per cent. 7.60	per cent. 12.14
(b) Free lime (Sugar Method).....	0.84	2.30	3.08	2.03	1.20	1.60	1.44
(c) (a) + (b).....	6.44	13.34	13.92	11.17	11.14	9.20	13.58
(d) Lime available as base ($\text{NH}_4\text{H}_2\text{SO}_4$ Method) (5½ hrs.).....	28.30	24.00	19.31	15.23	24.05	22.25	13.60
(e) Citric soluble lime.....	31.10	34.50	31.90	27.80	40.00	29.00	34.80
(f) (e) - Lime in citric soluble phosphate.....	25.50	23.46	21.06	18.66	30.06	21.40	22.60

In Table V. (a) the percentage of lime which might be liberated from the slag samples in this way is calculated, assuming that all the citric soluble phosphate consists of tetra-calcium phosphate. The free lime found by the sugar method is given in line (b). Table V. Line (c) shows the sum of (a) and (b), and line (d) the lime available as a base as found by distilling with ammonium sulphate for 5½ hours (Table III.). It will be seen that except in the case of slag No. 7, where they are practically equal, the figure in (d) is much greater than that in (c) for the same sample. Nor do the figures bear any constant relation to one another. By comparing Table V. with Table III. it will be found that the percentage of lime found by distilling with ammonium sulphate for 1½ hours is in four cases Nos. 1, 2, 5 and 6, considerably greater than the sum of the percentages of free lime and basic lime derived from the maximum amount of tetra-calcium phosphate which could be present. [(c) Table V.] It is evident then that all the lime in basic slag that can act as a base and drive off ammonia from ammonium salt cannot in most cases be accounted for by adding the free lime to the maximum amount of lime which can be liberated from basic phosphate. A

available as a base estimated by any of the methods given in Table III. Part of the citric soluble lime, however, is lime firmly combined with phosphate. If we assume that each molecule of phosphoric anhydride requires two molecules of lime for such close combination, and subtract this amount of lime from (c), the figures in (f), Table V., are obtained. These again bear no approximately constant relation to the lime available as a base determined by other methods.

All these figures indicate that the basic lime in slag is not only a very variable quantity, but that it consists of lime in various forms of combination. A little of it is free caustic lime. The rest is in combinations, such as silicates and basic phosphates. A part of this combined lime is readily liberated, and will probably readily act in the soil as a base. Other portions are only liberated with greater difficulty and slowly. As the conditions are very complex, it is impossible to draw any line and state an exact percentage of basic lime in slag except in terms of a strictly defined method of determining it.

In addition to thanking those who supplied me with samples, I have to acknowledge my indebtedness to a number of my advanced students, who carried out for me most of the determinations recorded in this paper. In particular I have to thank Mr. R. Ferries, B.Sc., on whom the bulk of the analytical work fell.

THE BEHAVIOUR OF WHEATEN FLOUR TOWARDS BAKERS' AND BREWERS' YEAST.

BY JULIAN L. BAKER AND H. F. E. HULTON.

The difference between bakers' and brewers' yeasts in their respective fermentative powers in doughs has long been known. Brewers' yeast is still said to be used to a considerable extent in the production of "country bread" and bread made in private houses, and it is supposed to produce a sweeter flavoured and moister loaf than bakers' yeast. Since the public now demand that bread should have a white and even texture and be free from any bitter flavour, brewers' yeast is practically unused in the bread-making industry in this country.

C. J. Lintner (Woch. f. Brau., 1901, 18, 446; this J., 1901, 1128) was the first to point out that pressed bottom fermentation yeast was far less resistant to high temperatures than bakers' yeast; when it is used the dough rises rapidly to the proper height but falls down again during the baking, and the bread lacks the desired porosity. Solutions of cane sugar were fermented with different yeasts by this observer, and it was shown that low fermentation brewers' yeasts were weakened to a much greater degree by temperatures above 86° F. than distillery yeasts.

Lintner suggested that this might be the reason of their different behaviour during baking operations.

A number of processes have from time to time been described for converting brewers' into bakers' yeast. If it can be done by any simple process the proposition is an attractive one, for brewers' yeast has practically no market value, whilst pressed bakers' yeast is worth £30 or more per ton. The conversion is possible—in fact, in some distilleries where a proportion of brewers' yeast is used it is done. The question then presents itself, Why is brewers' yeast so much weaker in fermenting dough than bakers' yeast, since there is no evidence to the contrary that the two yeasts belong to the same species of *Saccharomyces cerevisia*?

In view of the results obtained in a series of interesting investigations conducted by H. Lange* and F. Hayduck

* With regard to the presence of toxic substances in flour, Jazo has recorded (Science and Art of Breadmaking, 1895, p. 223) experiments in which he shows that brewers' yeast, while quite as capable of fermenting sugar solution as distillery yeast, is relatively inactive towards a mixture of flour and water. When flour and sugar were mixed, even the gas yield from the sugar was inhibited. He states "that flour also exerted a retarding influence on the fermentation with distillers' yeast." Attempts were made to discover what part of the flour exerted this retarding action on brewers' yeast, and he decided that it was the gluten. It was also noticed that brewers' yeast destroyed the viscosity of the gluten more than did the distillers' yeast.

the presence of toxic substances in cereals, we have tried that some light might be thrown on the reason for the difference between the two yeasts by allowing them to ferment doughs under varying conditions of ironment.

F. Lange (Woch. f. Brau., 1907, 24, 417, 433, 445, 457, 489, 505, 521; this J., 1907, 1104) and F. Hayduck (Woch. f. Brau., 1907, 24, 673, 685, 706, 746; this J., 108, 85) have shown that many cereals exert a toxic effect on yeast which the presence of certain substances can overcome, and in the experiments that follow we hope to make it evident that the difference in the behaviour of brewers' and bakers' yeast in flour fermentation is due to the susceptibility of the former and the immunity of the latter to this poison. A partial acquired immunity can be conferred on brewers' yeast by the use of certain salts, thus enabling it to approach, though never to equal, the activity of distillers' yeast when allowed to ferment in dough under similar conditions.

Experimental.—A series of six wide-mouthed 250 c.c. bottles were fitted with rubber stoppers carrying outlet tubes. The carbon dioxide was led from each bottle to a small flask filled entirely with strong brine solution so that the least evolution of gas displaced a corresponding volume of solution of salt into a graduated vessel. The temperature was kept constant by immersing the bottles in a water bath. It is unnecessary to make correction for the solubility of carbon dioxide in the brine solution, as all readings are comparative, absolute volumes not being required. Unwashed pressed brewery ale yeast was used, varying in age from 50 to 70 hours. The bakers' yeast was an "Edinburgh whisky distillery yeast," and when used by us its age was also 50 to 70 hours.

The fermentations were carried out at 110° F., for, as shown by one of us (J. L. Baker, J. Fed. Inst. Brew., 1903, 489; this J., 1903, 1203), brewers' and bakers' yeasts do not greatly vary in their fermentative power towards sugar solutions at this temperature.

Throughout these experiments, unless stated to the contrary, the following conditions were kept constant:—50 grms. of flour (Hungarian) were stirred into an even paste with 50 c.c. of water, and 1 gm. of yeast was then thoroughly incorporated. The bottles and their contents were placed in a water bath maintained at a temperature of 110° F., and after standing for 5 minutes were connected with their respective flasks containing the saturated brine solution. Readings of the gas produced as indicated by the volume of the brine displaced were recorded at intervals of 2, 3, and 4 hours.

In the experiments about to be described it was obviously necessary to ascertain the volume of gas which had been derived from the soluble carbohydrates already existing in the flour used. The total sugar as "glucose" or inversion obtainable from 20 grms. of the flour by ether water extraction is 0.51 gm., which should yield on fermentation roughly 128 c.c. of carbon dioxide. Consequently if more than this volume of gas is obtained when carrying out a fermentation of flour-dough, there appears to be no escape from the inference that the maltose formed in the flour from the starch by the action of diastase is the source of the extra yield. More than this volume is obtained less than two hours when flour dough is fermented with brewers' yeast, the five hours' yield being 350 c.c. But with bakers' yeast, even with the protective help of potassium sulphate, the three hours' yield in our experiments never more than slightly exceeded the 130 c.c. derived from the ready formed sugar. This does not of course prove that no diastatic action occurred until after three hours, since fermentation of newly formed maltose and pre-existing sugar may have occurred simultaneously.

Essential differences between bakers' and brewers' yeast.

Fermentation of flour in distilled water.—When flour is mixed with distilled water and brewers' yeast there is practically no fermentation. Bakers' yeast, on the other hand, under similar conditions gives a considerable yield of gas. The following figures illustrate the point:—

Effect of distilled water.

Time in hours.	Carbon dioxide evolved.	
	Brewers' yeast.	Bakers' yeast.
	c.c.	c.c.
2	8	143
3	9	216
4	10	287

The total yield of carbon dioxide at the end of four hours being 10 c.c. in the one case, as against 287 c.c. in the other. In this connection it may be remembered that Lange, Henneberg, and others (Jahrbuch der Versuchs und Lehranstalt, 1904 and 1905) have shown that bottom fermentation yeast is susceptible to the action of toxic substances in cereals when the yeast and cereals are present together in saccharine solutions prepared with distilled water.

Effect of tap or supply water.

The laboratory supply water used in these experiments contained, in grains per gallon: Total solids, 21.42; solids after ignition, 19.74; SiO₂, 0.28; CaO, 7.6; MgO, 0.71; SO₃, 2.69; K₂O, 0.42; Na₂O, 1.26; Cl, 1.40; N₂O₅, 0.31.

When this water is substituted for distilled water there is a marked increase in the activity of brewers' yeast. The fermentative power of bakers' yeast is however, unaltered.

Time in hours.	Carbon dioxide evolved.	
	Brewers' yeast.	Bakers' yeast.
	c.c.	c.c.
2	23	158
3	30	224
4	35	287

Presence of inorganic salts in water.

These may be dissolved in distilled or tap water. The results show that a greater effect is produced on the fermentative activity of brewers' yeast towards flour by dissolving the salt or salts in tap water.

The following table shows the protective influence of different salts dissolved in tap water on brewers' yeast in the fermentation of flour. The "increased yield" is the number of c.c. of carbon dioxide more than the 33 c.c. yielded by the control. The weights of salt are expressed as a percentage on the weight of water (50 c.c.) used.

Salt.	Per cent.	Increased yield of carbon dioxide in 3 hours.
0.02 Potassium sulphate	0.02	6
0.2 "	0.2	52
0.6 "	0.6	102
1.2 "	1.2	122
2.0 "	2.0	135
0.02 Kainite	0.02	8
0.1 "	0.1	38
0.3 "	0.3	91
0.6 "	0.6	126
1.0 "	1.0	152
2.0 "	2.0	163
6.0 "	6.0	148
0.6 Potash alum	0.6	8
0.6 Rochelle salt	0.6	31
0.6 Potassium nitrate	0.6	80
0.6 Magnesium chloride	0.6	90
0.6 Potassium chloride	0.6	120
0.6 Potassium hydrogen phosphate	0.6	74
0.6 Potassium dihydrogen phosphate	0.6	25
0.6 Sodium chloride	0.6	105

Potassium sulphate, calcium chloride, sodium chloride, and many other salts all act as accelerants. For experimental purposes we have used potassium sulphate as this materially enhances the fermentative power of brewers' yeast. The following table shows the gas production of brewers' and bakers' yeast when the flour was doughed with an aqueous (tap or distilled) solution of potassium sulphate containing 0.6 grms. per 100 c.c.

Effect of potassium sulphate dissolved in distilled and tap water.

Yeast.	c.c. of carbon dioxide evolved in 3 hours.			
	0.6 per cent. potassium sulphate in			
	Distilled water.	Tap water.	Distilled water.	Tap water.
Brewers' yeast	9	29	47	133
Bakers' yeast	240	212	221	204

The accelerating effect of tap water on brewers' yeast is probably due to the presence of acid calcium carbonate, for we have found that a solution of this salt prepared in the laboratory, when diluted with distilled water so as to contain the same amount as is present in tap water, yielded the same volume of gas as flour, brewers' yeast, and tap water.

Ford and Guthrie (*J. Inst. Brewing*, 1908, 14, 61; this *J.*, 1908, 239) drew attention to the protective or stimulating action which some inorganic salts exert upon barley diastase. Experiments we have made on the activation of flour diastase by the use of potassium sulphate and sodium chloride show that the Lintner value can be raised from 29 to 42 by their use. But a distinction must be drawn between the two functions that such salts appear to possess, viz.: (1) that of diastatic activation and (2) that of toxin counteraction. That the increased yield of carbon dioxide obtained by the use of potassium sulphate in the foregoing experiments with brewers' yeast is due to the second of these two properties we think is emphasised by the three following considerations.

(1) The use of the salt does not result in an increased yield of carbon dioxide when bakers' yeast is employed to ferment flour.

(2) Without the use of some such salt only about one-tenth part of the gas due from the existing carbohydrates in the flour is obtainable on fermenting a flour dough with brewers' yeast and distilled water.

(3) The toxicity to brewers' yeast of cold water extract of flour is overcome by the use of potassium sulphate. Here there can be no possibility of an activated diastase producing more maltose and consequently an enhanced gas yield.

So far we have shown the marked differences in the behaviour of brewers' and bakers' yeast towards flour. Whilst the gas yielded from bakers' yeast is practically unaffected by the presence of certain salts, that from brewers' yeast is greatly augmented. We have thus a means of readily distinguishing between the two yeasts. This well-defined difference between the two yeasts suggests that they may be of a different race although this is not in harmony with the fact that distillers can ferment their worts with brewers' yeast and the crop off this is suited for baking purposes. It may be urged that in such a case only those cells which can reproduce readily in the presence of toxic substances in the distillers' wort survive and that what has really taken place is a fractionation of the brewers' yeast. The action of potassium sulphate and other salts in raising the gas yield of flour and brewers' yeast is thus one of "protection" of the yeast against the toxic substance in flour. Bakers' yeast having been grown in a medium containing a toxic substance of a nature similar to that in flour has no need of protection, and the gas yield is not augmented when such a yeast ferments flour. These considerations led us to make experiments to ascertain if it is possible thus to select out

from brewers' yeast a strain having the characteristics bakers' yeast.

Brewers' yeast was successively grown in distiller wort three times, the yeast crop from the first fermentation being used for the second fermentation, and so on. The gas yields below show that the resulting yeast no longer requires the "protective" influence of salts.

c.c. of carbon dioxide evolved in 3 hours.

	Brewers' yeast grown three times in distillers' wort.	Ordinary brewers' yeast.	Bakers' yeast.
Distilled water ...	188	7	240
Tap water	206	30	212
Tap water containing 0.6 per cent. of potassium sulphate	204	134	204

Having thus succeeded in obtaining a new strain bearing the characteristics of bakers' yeast, the next point was to ascertain if these characteristics are permanent. Some of the yeast was therefore grown three times in ordinary brewers' hopped wort and submitted to the test described above:—

c.c. of carbon dioxide evolved in 3 hours.

	Brewers' yeast grown three times in distillers' wort and three times in brewers' wort.	Ordinary brewers' yeast.	Bakers' yeast.
Distilled water ...	160	7	240
Tap water	172	30	212
Tap water containing 0.6 per cent. of potassium sulphate	160	134	204

Although the volumes of gas yielded by the yeast after being re-grown in brewers' wort are not so great as before, yet the characteristic of the yeast is maintained, that is to say, that potassium sulphate is unable to exert an accelerating influence.

As a result of the investigations described in this paper we believe we are justified in putting forward the following suggestion as to the reason of the difference between the two yeasts:—

In a distillery wash, before the yeast is introduced, there are present large quantities of raw cereals, such as barley and rye, containing toxins, and since the distiller pitches his yeast into unboiled wort and therefore one with the cereal poison still active, only those yeast cells which can survive and are immune to such toxic substances and can reproduce in this environment will carry on the race, giving rise to cells inheriting this advantageous variation. There will thus be obtained in a few generations by natural selection what is to all intents a new species bearing this character of immunity to cereal poison. When such yeast is used for bread making, where it is again exposed to the action of the toxic substance in wheaten flour, the high gas yield at once shows that it is now immune, while brewers' yeast which has always been grown in a boiled, and therefore non-poisonous wort, is readily susceptible. The accelerating influence of potassium sulphate, sodium chloride, etc., on the fermentation of flour with brewers' yeast is thus seen to be correlated with the protective function these salts exert on the yeast by negating the toxic effect of the flour, while distillery yeast which is already immune to these toxins from having been grown in their presence, needs no such protection, and is, in fact, not activated by these salts.

Conclusions.

1. The existence in flour of a substance toxic to brewers' top fermentation yeast is confirmed, the poisonous action

ing greatest in presence of distilled water, less in supply
ater, and largely counteracted by potassium sulphate
d some other salts.
2. Bakers' yeast is unaffected by the flour toxin, and
ments with equal readiness doughs prepared with
stilled, tap, or hardened water.
3. The increase in fermentative power shown by
ewers' yeast in presence of potassium sulphate is not
ie to the activation of the flours' diastase but to the
hibition of the cereal toxin.
4. Bakers' yeast is unable to ferment more than a
uall fraction of the existing carbohydrates in flour
hen the dough is made with distilled water.
5. Brewers' yeast, on being grown consecutively three
mcs in a whisky-mash wort was found to have the
operties of a bakers' yeast, such properties showing
it little deterioration when the yeast was grown suc-
essively three times in a brewers' hopped wort.
6. Bakers' yeast seems to owe its toxin immunity to
e fact that it has been produced in a wort made from
cereals, such as barley and rye, containing toxins, only
ose cells that can reproduce in such an environment
urviving and transmitting this selected immunity to the
op collected. Such yeast will exhibit a much greater
ermentative power in presence of flour toxins than a
ewers' yeast grown in a boiled and therefore non-
poisonous wort.

THE TOXICITY OF FLOURS TOWARDS SACCHARO-
MYCES CEREVISIÆ (TOP FERMENTATION
BREWERY YEAST).

BY JULIAN L. BAKER AND H. F. E. HULTON.
In the previous paper we have shown that the reason of
the difference in the fermentative power of bakers' and
ewers' yeast in a medium of flour and ordinary water
ould appear to be the susceptibility of the latter to
the toxic bodies which are present in the flour. Distillery
east which is used by bakers is the outcome of repro-
uction in a medium in which only those cells that are
immune to the toxicity of an unboiled cereal wort can
urvive and reproduce. Hence distillers' yeast has a
uch greater immunity to the toxic properties of flour
an brewers' yeast.
This paper is the outcome of a further investigation on
the effect of the toxic substances in wheat flour on
saccharomyces. Since the marked difference in ferment-
ative capacity in flour-dough of the two yeasts which we
ave already discussed does not extend to their action on
vert sugar, it was thought probable that by the investi-
ation of the behaviour of the two yeasts towards different
ermentable media we might find some common factor
hich could be regarded as assisting in an inhibiting action
a brewers' yeast.

Fermentations with brewers' and bakers' yeasts were
arried out with—1. Invert sugar. 2. Aqueous flour
tract. 3. Invert sugar and flour. 4. Aqueous flour
tract and flour. 5. Distillers' wort (malt maize and
ye). 6. Cold aqueous extract of distillers' malt. 7.
nboiled malt wort prepared from brewers' malt.
The apparatus used in these experiments was the same
as that described in the previous paper. 20 grms. of
our were stirred into an even paste with 50 c.c. of solution,
grm. of pressed yeast was then incorporated and the
ermentation carried out at a temperature of 110° F.
1. *Invert sugar*.—The following results show that
akers' and brewers' yeast behave alike to a solution
f invert sugar. 50 c.c. of a 2.0 per cent. solution of the
ugar in distilled water was fermented at 110° F. with
akers' and brewers' yeast.

Yeast.	2.0 per cent. invert sugar in distilled water (50 c.c.).	
	c.c. carbon dioxide evolved in	
	3 hours.	4 hours.
akers'	85	112
ewers'	91	113

In the presence of potassium sulphate the yield of gas
from brewers' yeast when fermenting invert sugar is
practically unaltered.
2. *Flour extract*.—It was thought that the substance
which is toxic to brewers' yeast might be partially soluble
in water. 20 grms. of flour were extracted with 100 c.c.
distilled water for four hours at the ordinary temperature
and filtered. 50 c.c. of this extract contains the soluble
matter in 10 grms. of flour.

Yeast.	c.c. of carbon dioxide evolved in 3 hours.	
	Flour extract alone. 50 c.c.	Flour extract. 50 c.c. with potassium sulphate.
Bakers'	70	67
Brewers'	42	68

Here from the extract of 10 grms. of flour fermented with
brewers' yeast 42 c.c. of carbon dioxide are obtained, but
when this yeast ferments a mixture of the same flour and
distilled water it only produces about 7 c.c. of carbon
dioxide. The fact that the fermentative power of the
brewers' yeast towards flour extract is raised by the
addition of an inorganic salt indicates that a toxic substance
is present. When flour is extracted with tap water the
extract shows no evidence of toxicity, the yield of gas with
brewers' and bakers' yeast being similar. This is no doubt
due to the protective influence of the dissolved salts.
3. Jago (Science and Art of Breadmaking, 1895) has
stated that the presence of flour will inhibit the fermenta-
tion of a solution of sugar. We thought it well to examine
this point somewhat more closely. A 2 per cent. solution
of invert sugar in distilled water was prepared, 50 c.c.
of which should yield about 170 c.c. of carbon dioxide.
Brewers' yeast was used.

c.c. of carbon dioxide yielded in 3 hours.					
Distilled water.			Distilled water containing 0.6 per cent. of potassium sulphate.		
50 c.c. of invert sugar solution.	50 c.c. of sugar solution + 20 grms. of flour.	20 grms. flour.	Sugar.	50 c.c. sugar solution + 20 grms. flour.	20 grms. flour.
94	13	9	96	61	50

The results clearly show that the fermentation of the
sugar is stopped by the flour and also that the protective
influence of potassium sulphate on the mixture of sugar
and flour is very great.
4. Flour will also inhibit the fermentation by brewers'
yeast of its own aqueous extract just in the same way that
it does invert sugar. The flour extract was prepared by
digesting 20 grms. of flour with 100 c.c. for several hours.
50 c.c. of the extract was used in the experiment.

c.c. Carbon dioxide evolved in 3 hours.	
Brewers' yeast.	
(a) Flour + tap water	29
(b) Flour extract (50 c.c.)	36
(c) Flour (20 grms.) + flour ex- tract (50 c.c.)	32

The gas yield from "c" should be the sum of "b"
and "a" (36+29), that is 65 c.c. Only half of this
volume being obtained shows that the flour has retarded
the fermentation of the flour extract.

A similar experiment carried out with bakers' yeast demonstrated that flour had no retarding effect on the fermentations of its own extract. The gas yield of the flour plus its own extract was equal to the sum of the yields of the flour itself and its extract.

5. Since brewers' hopped wort may be regarded as the natural medium for brewers' yeast, it appeared to us of interest to ascertain how brewers' yeast would ferment a distillers' wort which is unboiled. A wort was prepared by mashing a mixture of distillers' malt (diastatic power, 130° Lintner) 28 per cent., rye flour 36 per cent., and flaked maize 36 per cent., at 130° F. for an hour.

Yield of carbon dioxide (brewers' yeast).

Hours.	10 c.c. wort + 40 c.c. distilled water.	10 c.c. wort + 40 c.c. tap water.	10 c.c. wort + 40 c.c. tap water containing 0.6 per cent. potassium sulphate	10 c.c. wort + 40 c.c. tap water containing 0.6 per cent. sodium chloride.
3	33	71	80	84
5	39	99	113	118
17	39	145	143	148

The poisonous effect of the wort in presence of distilled water is marked, also the protective influence of the dissolved salts. The yeast in the latter case was vigorous and healthy and in contrast to that from the fermentation carried out in presence of distilled water. Lange has shown that rye is toxic to bottom fermentation yeast, and the last experiment shows that English top fermentation yeast is similarly affected.

6. So far there is ample evidence that certain cereals contain a substance which is toxic to brewers' top and bottom fermentation yeast. Lange has closely investigated the properties of this poisonous body, but up to the present there are no data which throw much light on its chemical or physical properties. The suggestion that it may be oxalic acid seems negated by the fact that so many neutral salts like potassium chloride, sodium chloride and potassium sulphate, can prevent the toxic effect on brewers' yeast. The fact that boiling destroys the toxicity of an extract suggested a protein carrier for the poison and it was thought that by digesting at 110° F. with its own active protease a wort which was poisonous to brewers' yeast the toxic substance, if present, might be broken down and its toxicity diminished or destroyed. Distillers' malt (diastatic power 120° Lintner) was extracted our hours with three times its weight of cold distilled water and filtered. A portion of the filtrate was digested at 110° F. for three hours, another portion was fermented at once, and a third portion was boiled before fermentation to destroy the diastase and toxic substance.

Yield of carbon dioxide (brewers' yeast).

Hours.	Undigested malt extract.			Malt extract previously digested for 3 hours.		
	Alone. 50 c.c.	Wort containing 0.6 per cent. potassium sulphate 50 c.c.	Boiled wort 50 c.c.	Alone. 50 c.c.	Wort containing 0.6 per cent. potassium sulphate 50 c.c.	Boiled wort 50 c.c.
3	44	74	92	59	90	96
4	51	90	114	72	112	116
10	53	127	142	77	155	140

The double effect of previous digestion and potassium sulphate protection brings up the gas yield to that of the boiled and therefore non-toxic solution.

Here, as in the fermentation of flour by brewers' yeast, the protective action of potassium sulphate is well shown. Fermentation of the digestion products of the malt extract

shows a somewhat increased yield of gas, but it is no possible to state with certainty if digestion has weakened the toxic substance by bringing about proteolysis, or if it is partially coagulated at the temperature of the experiment.

7. A pale English malt (diastatic power, 29° Lintner) was mashed at the rate of 10 grms. per 100 c.c. with (i.) distilled water; (ii.) tap water.

50 c.c. were fermented with brewers' and bakers' yeast alone and with the addition of potassium sulphate

c.c. Carbon dioxide evolved in 3 hours from 50 c.c. of wort.

Brewers' yeast.

Malt mashed in distilled water.	Malt mashed in tap water.	Malt mashed in tap water and 0.6 per cent. potassium sulphate added before fermentation.
168	191	176

Bakers' yeast.

Malt mashed in distilled water.	Malt mashed in tap water.	Malt mashed in tap water and 0.6 per cent. potassium sulphate added before fermentation.
187	192	193

It is evident that there may be a small amount of toxicity in the mash made with distilled water, since the yield of gas with brewers' yeast is smaller than when a mash made with tap water is fermented. Both yeasts behave alike when the wort made with tap water is fermented.

From an inspection of the foregoing experiments it would appear that it is not malting that restricts the toxicity of these cereals, but the heat to which they are subjected on the kiln after germination, as the distillers' malt wort which is air dried still retains much of the yeast poisoning qualities which have disappeared in the wort prepared from such lightly cured malt as that used in the last experiment.

The net result of these fermentations described above is to show that raw and even malted cereals contain a substance which is toxic to brewers' yeast, partially soluble in water, and in all cases capable of counteraction by salts. Our next experiments were accordingly conducted with the object of forming some idea as to the nature of the toxic substance present in flour. A summary of the work which had been done up to 1906 may be found in the Journ. Inst. Brew., 1906, 12, 666 (see this J., 1907, 61), in a paper by H. Lange, Henneberg, F. Hayduck and Wendel. With regard to the characterisation of the poisonous substance in cereals these authors state "that it can be destroyed in rye grits by heating for several hours at 100° C. The same effect is produced by boiling the poisonous extract, although in some cases the toxic action is only weakened. When a cereal is malted the toxic action is weakened, but it is yet undetermined whether it can be entirely destroyed. The toxic substance cannot be extracted by any of the customary chemical methods. This suggested that the toxic substance must be sought amongst the proteins, or it may be produced from the same by the activity of the yeast." We also find that after a flour is heated its toxic influence towards brewers' yeast is lessened. Flour was heated to 210° F. and kept in a moist atmosphere until the original moisture was absorbed again. The gas yielded by brewers' and bakers' yeast in the fermentation of the unheated and heated flour was then measured.

c.c. Carbon dioxide evolved in 3 hours.				
Yeast.	Distilled water.		Tap water containing 0.6 per cent. potassium sulphate.	
	Unheated flour.	Heated flour.	Unheated flour.	Heated flour.
Brewers' yeast.....	10.5	73	124	135
Bakers' yeast.....	200	152	237	157

The figures under the heading "Distilled water" show great improvement in the gas yield by brewers' yeast. There is no doubt to the destruction by heat of some of the diastatic material in the flour; but when bakers' yeast is employed, which is immune to this poison, heating the flour merely weakens the diastase, and so diminishes the amount of maltose formed from the starch without any compensating advantage, a considerably lower gas yielding the result. Turning now to the hardened waters, which benefit the brewers' yeast but not a bakers', it is evident that the protective action of the potassium sulphate is more than sufficient to mask the gain to the brewers' yeast due to heating the flour, but cannot compensate the bakers' yeast for the loss of diastase in the heated flour as is evidenced by its low gas production. It was thought that some indication of the nature of the toxic substance in flour might be gathered by fermenting the latter with brewers' yeast in presence of a general poison such as potassium cyanide and ascertaining under such conditions potassium sulphate still continues to exert a protective influence. A series of observations were made with brewers' yeast, the results of which are tabulated below:—

c.c. carbon dioxide evolved in 3 hours.					
20 grms. of flour + 50 c.c. of tap water.	20 grms. of flour + 50 c.c. tap water containing 0.01 gm. potassium cyanide.	20 grms. of flour + 50 c.c. tap water containing 0.3 gm. potassium sulphate.	20 grms. of flour + 50 c.c. water containing 0.01 gm. potassium cyanide and 0.3 gm. potassium sulphate.	20 grms. of flour + 50 c.c. tap water containing 0.05 gm. potassium cyanide.	20 grms. of flour + 50 c.c. tap water containing 0.05 gm. potassium cyanide and 0.3 gm. potassium sulphate.
34.5	39.5	130	112	15	18

It will be seen that when the amount of potassium cyanide used was insufficient to check the normal fermentation of flour by brewers' yeast as seen in columns 1 and 2, the addition of potassium sulphate only caused an increase in gas of 72.5 c.c. (112—39.5) in the presence of cyanide, instead of the increment of 95 c.c. (130—34.5) in its absence. Further, when, as in columns 5 and 6, an amount of potassium cyanide is used which seriously diminishes the gas yield, the addition of potassium sulphate exerts no protective action. As Lange and others working with him have stated that rye is very poisonous in its action towards yeast, it was thought it would be of interest to compare its effect in this respect with wheat flour.

Rye flour.			
Yield of carbon dioxide in one hour.			
Yeast.	Distilled water.	Tap water.	Tap water + 0.6 per cent. potassium sulphate.
Brewers' ..	c.c. 33	c.c. 48	c.c. 91
Bakers' ...	154	—	154

As the gas yield is very rapid when rye flour is fermented with bakers' yeast, it was not possible to record

the three hours' figure, but the figures are quite sufficient to show the immunity of the bakers' yeast and the great susceptibility of the brewers' yeast to the weakening effect of rye flour.

A cold water extract of rye in distilled water was prepared at the rate of 10 grms. per 100 c.c. This is very viscous and filters with difficulty. The following yield of carbon dioxide was obtained from 50 c.c. of the solution corresponding to 5 grms. of rye flour.

Bakers' yeast.			
50 c.c. + 0.6 per cent. potassium sulphate.		50 c.c. + 0.6 per cent. potassium sulphate.	
Hours.	50 c.c.	50 c.c.	50 c.c.
2	54	54	44
3	68	69	55
4	87	91	74

These results afford but slight evidence of a substance soluble in water which acts as a poison to brewers' yeast, in this respect differing considerably from wheat flour extract (*q.v.*).

The considerable extra yield of carbon dioxide obtained from wheat-flour dough and bakers' yeast when a trace of powdered malt (1 part in 400) is added was pointed out in our paper, "Considerations Affecting the Strength of Wheat Flours" (this J., 1908, 27, 368—376). We there attributed the extra yield to the starch liquefying enzyme of the malt. However this may be, no increase is obtained by the use of malt in the above proportions when brewers' yeast is substituted for bakers'.

It will be remembered that in all the experiments above described 20 grms. of flour are doughed with 50 c.c. of

water. The effect upon the gas yield of altering this ratio is very marked, as will be seen from the following figures. The weight of flour is 20 grms. in all cases:—

Yield of carbon dioxide in 3 hours.				
Yeast.	Distilled water.			Percentage decrease in gas yield.
	25 c.c.	50 c.c.	100 c.c.	
Brewers'	23	9	9	61
Bakers'	274	216	130	53

Yeast.	Tap water.			Percentage decrease in gas yield.
	25 c.c.	50 c.c.	100 c.c.	
Brewers'	72.5	40.5	21.5	66
Bakers'	270	224	182	33

Here the decrease in gas yield expressed as a percentage, is the fall when the 100 c.c. yield is compared with that from 25 c.c.

The following experiment was performed to see what was the relative efficiency as a protective agency of the

calcium carbonate in tap water as compared with the ash of the flour itself:—

Two portions of cold water extract from 20 grms. of flour were burnt and the ash (0.06 gm.) was added to a dough made with (1) distilled water; (2) tap water; fermentations being then carried out in the usual manner.

Yield of carbon dioxide in 3 hours. Brewers' yeast.			
1.	2.	3.	4.
Distilled water.	Tap water containing 0.008 gm. calcium carbonate.	Distilled water + 0.06 gm. flour ash.	Tap water + 0.06 gm. flour ash.
12	42	78	94

A calculation will show that in corresponding dilutions calcium carbonate is about 3.5 times as effective as the ash of flour in increasing the yield of gas in the presence of distilled water, or, in other words, in affording the yeast protection.

Conclusions.

1. Bakers' and brewers' yeasts behave alike to invert sugar, the yield of gas not being augmented by potassium sulphate.

2. Flour extracted with distilled water yields an extract toxic to brewers' yeast. This toxicity can be overcome by potassium sulphate.

3. Fermentation of a sugar solution by brewers' yeast is stopped by the addition of flour. In the presence of potassium sulphate the fermentation proceeds.

4. Fermentation by brewers' yeast of the aqueous extract of flour is retarded by the addition of flour. Flour or its extract is without influence on the fermentative energy of bakers' yeast.

5. A distillers' wort prepared from malt, rye flour and maize is toxic to brewers' yeast, the toxicity being destroyed by boiling. Whilst heating to high temperatures on the kiln effects the destruction of the toxicity of barley malt, the process of germination does not. When flour is heated to 100° C. for some hours the toxicity previously exhibited towards brewers' yeast is considerably reduced.

6. Flours were fermented with brewers' yeast in the presence of an amount of potassium cyanide which lowers the gas yield. The addition of potassium sulphate exerts no protective action.

7. Brewers' yeast is very susceptible to the weakening effect of rye flour. The toxins present, unlike those of wheat flour, are not soluble to any considerable extent in water.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southamptton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Evaporating liquid from brine for the production of salt or for evaporating liquid from other solutions. J. Hodgkinson, Manchester. Eng. Pat. 5011, March 5, 1908.

In order to maintain a uniform temperature in the furnace below the closed brine-pan, the fuel is fed by an automatic coking stoker of the type known as the Hodgkinson stoker. The separated salt is removed from the pan by rotary rakes which deposit it in an external depression from which it is elevated and discharged. The foam is broken by a rotating film breaker partially immersed in the brine. Both the steam from the finishing pan and the waste gases from the furnace may be used in auxiliary pans through which the fresh brine flows and receives a preliminary heating and concentration before it reaches the finishing pan.—W. H. C.

Coolers or condensers also applicable for use as heaters or evaporators. J. Grouvelle and H. Arquembourg, Paris. Eng. Pat. 13,776, June 29, 1908. Addition to Eng. Pat. 10,143 of 1902.

The claim is for the substitution of tubular for the solid partitions which bear against the wings or gills of the tubes.—W. H. C.

Washing, separating, or concentrating minerals or substances of different specific gravities [coal, &c.]. G. H. Tarver and M. Coulson and Co., Ltd., Spennymoor, Durham. Eng. Pat. 12,077, June 3, 1908.

The claim is for improvements in the rotary washer described in Eng. Pat. 2482 of 1896. A number of longitudinal fins or plates are attached to the interior of the rotary cylinder between the spiral conveyor rims. The material is lifted by the plates and then, as the cylinder rotates, is thrown across the cylinder.—W. H. C.

Compressing air or gases, and apparatus therefor. H. Humphrey, London. Eng. Pat. 12,565, June 11, 1908.

WATER flows from the overhead reservoir, 3, down the pipe, 2, and past the valve, 5, through the pipe, 4, into the lower reservoir, 6. As soon as the velocity of the water is sufficient to overcome the tension of the spring, the valve, 5, closes and the water fills the part of the tube marked 1, the air-inlet valve, 7, closes, and the water is compressed until the pressure is great enough to open the outlet valve, 8. The compressed air is then forced out of the valve, 8, until the water reaches the lower end of the pipe, 10, until the valve, 9, closes. The compressed air contained in that portion of the pipe, 1, which is above the bottom of the pipe, 10, then expands and forces the water backwards until the pressure due to the velocity has been overcome, when the valves, 5, and 7, open again, the water flows away through 5, and a fresh charge of air enters through the valve, 7.—W. H. C.

II.—FUEL, GAS, AND LIGHT.

- Coal gas; Analysis of — and of similar gaseous mixtures, with special regard to the determination of nitrogen.* G. von Knorre. Chem.-Zeit., 1909, 33, 717–719.

A MODIFICATION of Jäger's method (J. Gasbel., 1898, 764) is described. After absorption of carbon dioxide, heavy hydrocarbons, oxygen, and carbon monoxide in the usual manner, the whole gaseous residue is passed over copper oxide in a quartz tube, heated to 250° C. The air in this tube is previously displaced by pure nitrogen which is led through by means of a capillary side-tube. At 250° C. the copper oxide oxidises the free hydrogen in the gas very rapidly to water; the gas is therefore passed to and fro through the heated tube until no further diminution in volume occurs. The total diminution in volume is equal to the volume of hydrogen originally present. The quartz tube containing copper oxide is then heated to bright redness and the gas passed to and fro until no further contraction occurs after contact with potassium hydroxide solution. The reduction in volume is equal to that of the carbon dioxide formed by the combustion of the methane in the residue, and therefore to the volume of $\frac{1}{2}$ methane itself. The residual gas represents the total nitrogen in the sample. Carbon monoxide is also oxidised to carbon dioxide by the action of copper oxide at 250° C. The copper oxide has to be occasionally regenerated by aspirating air through the heated tube for a few minutes. After a time, however, the regenerated copper oxide becomes inactive, and must be replaced. The quartz tube lasts for a long time. The results are said to be very accurate, as the total sample is used for all determinations and the quartz tube does not alter in volume by deformation on heating. For very accurate nitrogen determinations it is best to take a separate sample, pass it directly through the red hot copper oxide tube till no further contraction occurs and read off the volume of nitrogen which remains.—E. F.

- Oxyhydrogen flame; Temperature of the —.* E. Bauer. Compt. rend., 1909, 148, 1756–1757.

THE temperature of an almost homogeneous oxyhydrogen flame has been determined by two methods. (1). By measuring the emission and absorption of the flame for rays reflected from fluorspar, applying Planck's formula; this gives 2210° C. (2). By the method of the reversal of the D ray, by means of the electric arc and a system of absorbing prisms, which leads to values between 2260 and 2300° C., according to the proportion of oxygen.

—F. SODN.

- Illuminating efficiencies of carbon monoxide and hydrogen used in conjunction with incandescent mantles.* A. Forshaw. J. Gas. Lighting, 1909, 106, 865–871.

THE view widely held that the illuminating efficiency of a combustible gas used in conjunction with an incandescent mantle is proportional to its net calorific value appears to be based mainly on results obtained with more or less complex mixtures of gases (see this J., 1902, 1012, 1020; 1903, 1078, 1286). The author has compared the

illuminating efficiencies of hydrogen and carbon monoxide two gases not differing greatly in net calorific value, but exhibiting considerable differences in the character of their flames and their modes of combustion, the rate of combustion of hydrogen being very much higher than that of carbon monoxide, and the two rates being unequal accelerated by the influence of hot surfaces. It was found that in an ordinary atmospheric burner, it was not possible to burn a mixture of hydrogen with more than about one-fifth of the quantity of air necessary for complete combustion. Up to this point, namely a ratio of air to gas of 0.52, the duty (candles per cb. ft. of gas per hour) afforded steadily decreased with a rising rate of gas consumption. With this burner, carbon monoxide gave a very much higher duty than hydrogen, and the distribution of luminosity over the mantle was very different with the two gases. In order to be able to burn hydrogen in a well-aerated condition, a special burner was devised. The highest duty obtained therewith for hydrogen was 11.5 candles per cb. ft. with a ratio of air to hydrogen of 1.5; whilst the best result obtained with carbon monoxide (in the ordinary burner) was 17.3 candles per cb. ft. with a ratio of air to carbon monoxide of 1.9. The illuminating efficiency of carbon monoxide was thus 48 per cent. higher than that of hydrogen, whereas the calorific value under the experimental conditions, was only 13 per cent. higher. By using hollow cones of porous porcelain to confine the combustion as far as possible to a hollow she corresponding to the outline of the mantle, the combustion was accelerated and the illumination concentrated, but further experiments are needed to prove definitely whether the duty can be raised by this means.—A. S.

- Acetylene; Precautions in the preparation, storage, and use of — and storage of carbide.* Z. angew. Chem. 1909, 22, 1331–1332.

IN A decree issued by the Prussian Minister for Trade and Industry, it is stated that the exemption of small portable acetylene generators (charges of up to 2 kilos. of carbide) from the regulations in force with respect to the preparation and use of acetylene, has led to unforeseen results. Owing to the rapid development of autogenous welding in place of soldering, these acetylene generators are now used to considerable extent in closed workrooms and are frequently worked beyond their nominal capacity. The danger attending this state of things are referred to and a modification of the acetylene regulations is foreshadowed. In the meantime, exemption from the present regulation is to be limited to generators charged automatically with a definite quantity of carbide. Hand-worked generators which can be charged above their nominal capacity, and mechanically charged generators provide with means for feeding in several charges of 2 kilos. in succession are thus excluded, but permission for their use in closed workrooms may be granted in special cases. Where acetylene generators of any kind are used in workrooms, great care must be taken to avoid danger of injury to the workpeople, and special precautions must be taken when there is possibility of acetylene escaping into the room from the generator when it is in use.—A. S.

- Impurities in mine air due to the firing of dynamite.* Nauckhoff. See XXII.

PATENTS.

- Coal or coke dust or like fuel; Utilising — in furnaces fitted with mechanical stokers.* T. D. Stonehouse, S. Sampsons, Guernsey. Eng. Pat. 13,476, June 25, 1909.

LIQUID or solid hydrocarbons are fed in measured quantities into the hopper of a coking stoker, and are mixed with the fuel in the hopper. The finely divided fuel becomes agglomerated on the coking plate of the stoker and cokes into relatively large pieces which do not fall through the bars unburnt as would be the case with finely divided fuel if it were not agglomerated.—W. H. C.

- Peat products for fuel purposes, and process of manufacturing the same.* V. Zailer, Vienna. Eng. Pat. 1247, Jan. 18, 1909.

THE patent refers to a continuous process for the manufacture of enriched peat, in which the raw material is

orporated, in the cold, with mineral oil; tar and inferous oils are unsuitable. By incorporation with a thick peat pulp in a quick-running moulding machine the ordinary type, the oil becomes highly emulsified, and a homogeneous product is obtained in a single operation.—W. E. F. P.

onising air [for internal combustion engines]. H. C. Williams and G. W. Glascock, London. Eng. Pat. 17,325, Aug. 18, 1908.

The apparatus is intended for the rapid automatic production of large volumes of ozonised air to be used in internal combustion engines. A number of glass tubes, each closed at one end and provided with a core of corrugated metal of high electrical conductivity, are exhausted of air, and fixed in a frame of insulating material, such as opiate, the latter being enclosed in an outer casing of material suitable for attachment to the carburettor or mixing chamber of an internal combustion engine. The tubes are arranged in two groups, and, by means of wires soldered in the glass of the tubes, the two sets of cores are connected to the opposite poles of an induction coil. It is stated that by the use of ozonised air the explosive force of the fuel used in the internal combustion engine increased by 15 per cent. or more.—B. N.

Explosive mixture for combustion-engines. P. Winand, Cologne, Germany. U.S. Pat. 914,624, Mar. 9, 1909.

The explosive mixture (for use in the combustion-engines of submarines, torpedoes, etc., where atmospheric air is not available) consists of two non-explosive, nitrated carbon-compounds, together with a convenient diluent. One of the compounds (such as nitrobenzene) must contain sufficient oxygen for the complete oxidation of its carbon and hydrogen, and the other (such as tetranitroethane) a considerable excess of oxygen. The diluent serves for maintaining the required limitation of temperature and could preferably be provided by the products of combustion.—W. E. F. P.

Gas and coke oven plant. H. Koppers, Essen-Ruhr, Germany. Eng. Pat. 982, Jan. 14, 1909.

The ascension pipe, *a*, has an annular channel, *b*, formed at its upper end and is connected to the hydraulic main, *c*, at the bend, *c*, provided with a flange, *c'*, which dips into water contained in the annular channel, *b*, and forms a siphon. The hydraulic main has a short neck, *d*, formed at its upper side provided with an annular channel, *f*, to which the flange, *c'*, at the other end of the bend, *c*, is connected. The neck, *d*, is provided with a transverse

swivel damper, *h*, *g*, which is closed before the ascension pipe is disconnected. After disconnection a loose cover is placed over *d*. While the retorts or ovens are being charged or discharged, the ascension pipe is connected in a similar manner to a waste gas main, *i*, which is connected to the chimney stack.—W. H. C.

Retorts for the destructive distillation of coal; Discharging retort.—T. Parker, Wednesfield, Staffs. Eng. Pat. 14,165, July 3, 1908.

The retorts are arranged in sets, each of which is closed at the bottom by a single cover-plate operated from without the furnace. By lowering or withdrawing the cover-plate, the contents of each set of retorts falls on to one or other of the inclined walls of a kind of hopper several feet below, the impact being sufficient to break up the charge, which then passes through to a conveyor beneath.—W. E. F. P.

Coking plant. W. R. Elliott, Denver, Colo. U.S. Pat. 925,428, June 15, 1909.

The patent relates to a plant, for continuous working, in which the charge is supported on a movable platform, acting in conjunction with suitable quenching apparatus, and receptacles. The platform is charged from the coal-receptacle, transferred to the oven, and removed at the conclusion of the coking operation. After quenching, the mass is forced from the platform into the coke-receptacle.—W. E. F. P.

Coke-ovens; Bunsen burner for —, with detachable tube of refractory material. R. Müller. Fr. Pat. 397,325, Dec. 11, 1908.

In coke-ovens utilising the gaseous products as a source of heat, the metal burners employed, which are of the Bunsen type, require frequent renewal in consequence of the high temperatures to which they are exposed. In the present invention, the tube, or the head, of the burner is constructed of refractory material, and is easily detachable from the metal base.—W. E. F. P.

Coke-oven with vertical flues for ascending and descending gases. Dr. C. Otto and Co. Fr. Pat. 397,380, Dec. 14, 1908. Under Int. Conv., Dec. 19, 1907.

The coke oven described, which is of the regenerative type heated by gas from below, consists essentially of a series of coking chambers, separated by vertical flues, in which the hot gases ascend and descend successively. Alternate flues are provided with burners, each of which serves a pair of adjoining coking chambers, the hot gases being drawn into, and down, the remaining flues. The downward flow of the gases is regulated by means of dampers, uniform heating of the coking chambers being thus obtained. The construction of the oven varies according to requirements, provision being made for heating by means of gas, waste heat, or by gas and waste heat combined.—W. E. F. P.

Gas generators. A. Jabs, Zurich, Switzerland. Eng. Pat. 12,446, June 9, 1908.

In a shaft generator, more heat is generated in the lowest zone by the complete combustion of the fuel, than is required for the purpose of distilling the fresh fuel; this causes the gases and by-products to be drawn off in a highly heated state, the latter being decomposed into less valuable products. To avoid this, the generator is constructed with one or more lateral openings near the upper limit of the lowest zone, and about half of the coke is withdrawn as it is produced, leaving only sufficient incandescent coke to convert the carbon dioxide into carbon monoxide. The square section of the furnace is increased at the distillation zone, causing the fuel adjacent to the walls to become more rapidly coked, and therefore able to be withdrawn without intermixture with the partly distilled fuel.—F. R.

Gas-producer. G. Akerlund, Wilkinsburg, Pa. U.S. Pat. 925,415, June 15, 1909.

The apparatus consists essentially of a cylindrical coal receiver, closed at the top, and provided with a horizontal

vaporiser surrounding the ash-pot. The vaporiser communicates with the upper portion of the coal receiver by means of pipes extending longitudinally through the refractory lining of the latter, or the pipes may be replaced by an annular chamber in the said lining; and suitable means are provided for the admission of air, so that the heated mixture of air and steam is drawn from the top to the bottom of the fuel column. The gaseous products pass through openings in the bottom of the ash-pot into a cylindrical chamber beneath, and thence to the outlet.

—W. E. F. P.

Gas-producer. L. F. Burger, Assignor to J. Thompson and Sons, Beloit, Wis. U.S. Pat. 925,621, June 22, 1909.

THE claim is for a charging hopper for a gas-producer, provided with a conical drop-valve opening into the generator chamber and attached to a vertical reciprocating rod by which the valve is operated and which extends through the hopper. The latter has a sliding cover, which on being opened, engages the rod supporting the cone and locks it, so that the cone can only be lowered when the sliding cover is closed.—W. H. C.

Combustible gas; Process and apparatus for production of homogeneous —, by carburisation of atmospheric air. J. M. Arnold. Fr. Pat. 397,081, Dec. 4, 1908.

CARBURETTED air gas is often extremely variable in composition, since, in many methods of working, the most volatile constituents of the carburizing liquid are carried off in the earlier stages of the process, the heavier hydrocarbons remaining until the end. In the present process it is claimed that gas of constant composition, calorific power, and specific gravity may be obtained by means of the apparatus described. The carburizing liquid is automatically fed (in the predetermined proportion for the quality of gas required) into the carburettor, consisting of a long cylindrical chamber enclosing a vertical spiral. The liquid enters the top of the cylinder by means of radial, perforated pipes, and, falling on to the upper edge of the spiral, flows down the vertical surfaces of the same, where it is quickly and completely evaporated by an upward current of air issuing from similar pipes at the bottom of the chamber. The process is carried on under the constant pressure obtained by the action of the bell of a gasometer, which also serves to regulate the supply of carburizing liquid.—W. E. F. P.

Gas producer. L. Bénier. Fr. Pat. 397,206, Dec. 9, 1908.

THE apparatus consists of a cylindrical combustion chamber, lined with refractory material, and surrounded by a sheet iron envelope, enclosing an annular space through which the mixture of air and steam passes before coming into contact with the fuel. The circular grate supporting the latter slopes down from the circumference towards the centre, and is formed about a small annular chamber containing water, which serves to cool the grate and to generate the necessary steam. The fire-bars are placed radially, the central space being left free, thus forming a vertical pipe which is prolonged nearly to the bottom of the chamber beneath. The latter, serving as an ash-pit, communicates with a rectangular chamber containing a small boiler. The mixture of air and steam enters at the bottom of the annular space surrounding the combustion chamber, and passes into the latter through horizontal openings at the upper end. The gaseous product issues from the bottom of the furnace, and, passing into the rectangular chamber, gives up part of its heat to the small boiler contained therein, the heated water being subsequently fed into the small annular chamber forming part of the grate. The gas is then brought into contact with a spray of water, in order to free it from dust, and is finally passed through sawdust to complete the purification.

—W. E. F. P.

Suction gas producer for bituminous fuel. K. Herold. Fr. Pat. 397,278, Dec. 9, 1908.

THE producer consists of a cylindrical outer casing, provided with a grate, and within which is a cylindrical charging hopper, the upper end of which is widened to

meet the outer casing near the top, while the lower end extends to within a short distance of the grate, the intervening space being occupied, under working conditions, by a layer of incandescent fuel. In the middle portion of the charging hopper is fixed a smaller cylinder, open at the bottom, and provided with a horizontal pipe at the top (by means of which connection is made with the chamber beneath the grate, or with the outside air, and so placed that its lower end is about as far above the bottom of the hopper as the latter is above the grate. The chamber beneath the grate also communicates, by means of an outside pipe, with the top of the producer, and the gaseous products are drawn off at the upper end of the annular space between the hopper and the outer casing. When in operation, sufficient fuel is present to form a fairly thick layer on the grate, and to fill the cylindrical portion of the hopper. By suitable regulation, the gaseous products are finally made to pass upwards through the incandescent layer before being drawn off, the function of the innermost cylinder being to prevent tarry fumes, etc., from passing directly from the hopper to the annular chamber. This is effected by maintaining the interior of the cylinder and the annular chamber at about the same reduced pressure.—W. E. F. P.

Combustible gas; Production and regeneration of —, for fuel or motive power. J. Taverne. Fr. Pat. 397,285, Feb. 18, 1908.

CARBON monoxide is mixed with the required proportion of air (obtained from liquid air) to form a combustible mixture. After combustion the products are passed through incandescent coke in order to regenerate carbon monoxide.—W. E. F. P.

Electric lamp filaments; Manufacture of —, and apparatus therefor. Soc. Française d'Incandescence par le Gaz (Système Auer), Paris, France. Eng. Pat. 12,720, June 13, 1908. Under Int. Conv., July 13, 1907.

THE unfinished filament, composed of a metallic oxide, is inserted from the bottom into a vertical tube furnace, which is traversed by a current of reducing gas. The upper part of the furnace is strongly heated by gas or electricity. When the filament becomes a conductor, by the reduction of the metallic oxide to metal, a current of electricity is passed through it, completing the formation of the filament.—F. R.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Grossny petroleum; Optical and other properties of — M. Rakusin. Petroleum, 1909, 4, 921—924.

Crude oil.—On a former occasion the author determined the carbonisation constant (K) as 1/24 per cent. in benzene solution; and a recent examination of oil from a different depth gave the value, 3/32 per cent. *Laboratory fractions.*—The fractions up to 250° C. are colourless, free from dichroism, and give colour reactions with trichloroacetic acid, whilst the higher-boiling fractions show progressively deepening colour from straw yellow to blood red (the residue being black), and increasing dichroism. The oil behaves like other Caucasian oils on distillation, and contains 85 per cent. of recoverable fractions, 25.05 per cent. consisting of lubricating oil fractions. The heaviest of these fractions, coming over at 325°—340° C. (12 mm.), has the sp. gr. 0.9424 at 15° C., a viscosity equal to that of castor oil, and dextrorotatory power of about 80° in the saccharimeter. It is considered that the usual classification of petroleum residues according to their lubricating oil content, is based on the present defective method of practical distillation, and not on the nature of the crude oils. Specimens of lubricating oil, obtained by distilling about 8 cwt. of crude oil with superheated steam, would allow the rays of polarised light to pass only when examined in the form of solutions in benzene, of 6.25 and 3.12 per cent. concentration respectively; a result confirming the view that the practical distillation process requires modification, so that the distillates may be collected according to their boiling point limits and constants of rotation, thus enabling valuable technical products to be obtained with a minimum expense for fuel. *Residuum.*—The carbonisation constant (K) was only about four times as high as that of the crude oil, showing that no racemisation occurred in distillation. The optical examination of the residuum after refining with 30 per cent. of sulphuric acid, showed that the acid had greatly lowered the content of asphaltic constituents. *Behaviour of crude oil when centrifuged.*—This treatment reduced the specific gravity from 0.8791 to 0.8768, and raised the carbonisation constant from 3/32 per cent. to 1/8 per cent. These results are considered to throw light on the formation of asphaltum and similar products by the centrifugal force of the globe.—C. S.

Paraffin wax; Examination of — L. Singer. Petroleum, 1909, 4, 1038—1040.

PARAFFIN WAX of Austrian production is now so graded that it no longer consists of heterogeneous fractions, but of different grades, the melting and solidification points of which can be more or less sharply determined. For this purpose Shukoff's method is almost universally employed for commercial transactions (see this J., 1899, 406). For the determination of the proportion of oil in purified paraffin wax, Holde's modification is frequently used:—The weighed quantity (0.5 gm.) of the sample is dissolved in 30 c.c. of ether, and the solution mixed with 30 c.c. of 96 per cent. alcohol. The mixture is stirred and cooled to 20° C., and the insoluble portion separated and washed with 10 c.c. of a mixture in equal parts of alcohol and ether at 20° C. The residue on the filter is then washed with hot benzene or petroleum spirit into a weighed dish, the solvent evaporated, and the residue dried for 15 minutes at 105° C., and weighed. The filtrate and washings are also evaporated on the water-bath, and this residue washed with 6 c.c. of the mixture of alcohol and ether (this time cooled to —20° C.), and its weight added

to that of the previous residue. Finally the last filtrate and washings are evaporated, and the amount of residue obtained gives the proportion of "oil" in the paraffin wax. An addition of 1 per cent. must be made to the results thus obtained in the case of hard paraffins. The author has examined numerous samples of different grades of paraffin wax and has compared the results with the figures given by Shukoff's method. By dissolving the residues in 10 c.c. of petroleum spirit and treating the solution with alcohol and ether, as described by Holde, the proportions of "oil" are considerably lower. The following table gives typical results:—

Grade.	Solidification point.	Without petroleum spirit.		With petroleum spirit.	
		Paraffin.	Oil.	Paraffin.	Oil.
	° C.	per cent.	per cent.	per cent.	per cent.
White, soft (matsch)	44.9	90.02	9.98	91.90	8.10
50/51, opaque	50.3	98.10	1.90	99.80	0.20
50/51 transparent	50.6	98.93	1.07	99.78	0.22
60, transparent	58.6	99.55	0.45	100.00	0.00

From this it appears that the proportion of oil in a given grade of paraffin wax may be approximately the same in opaque and in transparent samples. In one case paraffin wax of undoubtedly transparent appearance contained as much as 3.6 per cent. of oil. This confutes the commonly accepted view that transparent paraffin wax must also be "free from oil," and that transparency may be accepted as the criterion of quality. Experiments made with Zoloziecki's method (which consists in dissolving the paraffin wax or paraffin oil in amyl alcohol and precipitating the paraffin with ethyl alcohol) gave analogous results. The author therefore concludes that all paraffins, including American and peat paraffins, have an "oil content" when examined by this method. Hence it would be advisable to adopt a commercially permissible limit for this proportion of "oil." This might well be fixed at 2 to 2½ per cent., and only in the case of soft paraffins for matches need an exception be made. A further difficulty in the examination of paraffin wax is that the methods of grading adopted in Germany, Scotland, and America do not agree, and a table is required showing the relationship between the Shukoff figures and those obtained by the Scotch and American methods of determination. The following table gives the present corresponding values, but in the author's experience these are not correct.

German method, ° C.	Scotch method, ° F.	American method, ° F.
38/39	98/102	101/105
45/46	110/112	113/115
48/49	115/	118/
50/51	118/120	121/123
51/52	118/120	121/123
53/54	125/127	128/130
56/57	130/	133/

PATENTS.

Tar; Device for preventing — from flowing with the ammoniacal liquor out of the tar well. R. Oetner. Ger. Pat. 210,590, May 26, 1908.

AN overflow pipe is provided through which the ammoniacal liquor floating on the tar in the tar well flows out into the liquor reservoir. At the bottom of the limb of the overflow pipe dipping into the liquor in the tar well is fixed a saucer with a hole in the centre and with several short inclined pipes projecting downwards between its centre and circumference. From the central hole a short conical pipe rises within the overflow pipe. As the ammoniacal liquor rises in the conical pipe and then in the overflow pipe, any entrained tar tends to settle and flow back down the outside of the conical pipe into the saucer, and thence through the short inclined pipes back into the tar well.—A. S.

Ammonium sulphat; *Saturator for the manufacture of* — H. Koppers. Ger. Pat. 210,902, April 3, 1908.

PERFORATED tubes are disposed within the gas space of the saturator and water is passed through these tubes in order to wet the walls of the vessel and so prevent the formation of crusts of salts thereon. Or, the gas space of the saturator may be surrounded by a cooling jacket, in which case water is condensed on the inner walls.—A. S.

Benzene hydrocarbons; *Process for purifying* — Badische Anilin und Soda Fabrik. Ger. Pat. 211,239, Sept. 5, 1907.

BENZENE hydrocarbons are purified from thiophen and its homologues by treatment with an aldehyde or an organic anhydride, in presence of a suitable condensing agent, and separating the purified hydrocarbon from the condensation product by distillation, etc. Formaldehyde, acetaldehyde, and phthalic anhydride are specially suitable for the process. The temperature and other conditions of the process should be so adjusted that the benzene does not enter into the reaction. 10,000 parts of benzene containing thiophen are agitated (for several hours) with a mixture of 1500 parts of 73 per cent. sulphuric acid and 45 parts of 30 per cent. formaldehyde, until a filtered sample does not react with a solution of isatin in sulphuric acid; the purified benzene may now be distilled with steam or by direct heat.—T. F. B.

IV.—COLOURING MATTERS AND DYESTUFFS.

Reduction of triphenylmethane dyestuffs and azo-compounds with sodium hyposulphite [hydrosulphit]. O. Fischer, A. Fritzen and S. Eilles. J. prakt. Chem., 1909, 79, 562—568.

THE authors describe examples of the advantage of using sodium hyposulphite in the reduction of dyestuffs (compare Grandmougin, this J., 1906, 805, 1142; 1907, 959). In this operation it is of distinct advantage to add a small amount of zinc dust which acts as a catalyst. *Crystal Violet*:—A solution of 5 grms. in 100 c.c. of alcohol is treated at the boiling point with a concentrated aqueous solution of 10—15 grms. of sodium hyposulphite, and 0.5 gm. of zinc dust is also added. On diluting with hot water and ammonia, a quantitative yield of hexamethylparaleucaniline is obtained. *Pararosanine*:—This is reduced in an exactly similar way. From the leuco-compound the following derivatives were prepared. Tribenzylidene-*p*-leucaniline, $C_{40}H_{31}N_3 + C_6H_6$, m.pt. 79° C.; the benzene-free substance melts at 175° C. Tribenzyl-*p*-leucaniline, m.pt. 106°—107° C. This, on oxidation with lead peroxide in acetic acid solution or by chloranil in alcoholic solution, yields tribenzylrosaniline, which is a red violet dyestuff. Tri-*o*-hydroxybenzylidene-*p*-leucaniline forms yellow needles, m.pt. 121° C. Tri-*p*-anisylidene-*p*-leucaniline forms colourless rods or needles, m.pt. 79—80° C. Tri-*p*-dimethylaminobenzylidene-*p*-leucaniline crystallises in bright yellow prisms, m.pt. 240° C. *Benzeneazo-ββ*-dinaphthylamine:—10 grms. are dissolved in a hot mixture of 200 parts of pyridine and 150 parts of alcohol, and a concentrated solution of 20 grms. of sodium hyposulphite added gradually. The whole is kept boiling and 5 grms. of zinc dust are added in small portions at a time. Then 20—30 grms. of hyposulphite and 5 grms. of zinc dust are added, whereby the solution becomes colourless. The pyridine-alcohol mixture is poured off, and on adding water, fine yellow needles of α -amino- $\beta\beta$ -dinaphthylamine are obtained. When this or its acetyl derivative (m.pt. 214° C.) is boiled with acetic acid, β -naphthylmethylethyl-naphthiminazole is formed.—J. C. C.

Thioindigo; *Some derivatives of* — Béchamp. Compt. rend., 1909, 148, 1677—1679.

THE author finds that, contrary to the experience of Sachs and Kantorowicz (this J., 1909, 594), the action of magnesium organic compounds on Thioindigo is simply

a reducing one: when decomposed by water the product of the interaction gives a white substance which rapidly oxidises to Thioindigo, and when treated with acetyl benzoyl chloride, the reaction product yields the acet derivative,

crystallising in fine white needles, m.pt. 218° C., or the benzoyl derivative,

which forms white felted needles, m.pt. 225° C. C saponification both compounds furnish leuco-Thioindigo —J. C. C.

Congo Red; *The osmotic pressure of* — and of some other dyes. W. M. Bayliss. Roy. Soc. Proc., 190 B, 81, 269—286.

It is found that Congo Red, although a colloid in the sense of not being diffusible through parchment-paper, has an osmotic pressure equal to that which would be given if it were present in true solution in single molecule. The theoretical osmotic pressure is only obtained in the absence of extraneous electrolytes. When these are present they cause aggregation of molecules to particles. The free acid of Congo Red forms a blue colloidal solution when dialysed: it gives an osmotic pressure of about 14 mm. of mercury for a 1 per cent. solution which, the kinetic theory be correct, means that the aggregate contains, on an average, 20 molecules.—J. C. C.

Indanthrene Blue and Indanthrene Violet as substitutes for ultramarine in sugar works. See XVI.

PATENTS.

Monoazo dyestuff; *Process for preparing a yellow* — Act. Ges. f. Anilinfabr. Ger. Pat. 210,598, April 1908.

2,3-DICHLORO-4-AMINOAZOBENZENE is converted into disulphonic acid by treatment with sulphuric acid containing 60 per cent. of anhydride, at 55°—60° C. The product dyes wool yellow shades fast to acids, and fast to light than the shades given by the known yellow azo dyestuffs.—T. F. B.

[Azine] dyestuffs for wool; *Process for preparing red* — C. Jäger. Ger. Pat. 210,702, July 21, 1908.

p-AMINOPHENOL- α -DISULPHONIC acid (prepared from nitrosodimethylaniline) is oxidised together with *m*-diamine to an indophenol, which is then converted in the corresponding azine by boiling in presence of an oxidising agent.—T. F. B.

Vat dyestuff; *Process for preparing a red* — Ges. Chem. Industrie in Basel. Ger. Pat. 210,813, June 2, 1907. Addition to Ger. Pat. 205,377, Jan. 17, 1907.

RED vat dyestuffs are obtained if, in the process described in the original patent (see Eng. Pat. 344 of 1908; this J., 1908, 399), the acenaphthenequinone is replaced by dichloroacenaphthenequinone,

and the oxythionaphthene by 3-oxy-(1)-thionaphthene-carboxylic acid.—T. F. B.

Vat dyestuffs; *Process for preparing green* — Ges. f. Chem. Industrie in Basel. Ger. Pat. 210,828, May 1, 1908.

DYESTUFFS which dye cotton fast, intense, green shades from the vat, are obtained by condensing inloxyl with derivatives of β -naphthhisatin of the formula,

ch as β -naphthisatin-naphthalide, mono- or dibromo- β -phthisatinchloride, etc., and treating the resulting estuffs with halogenating agents.—T. F. B.

izarindisulphonic acids; Process for preparing 3.5- and 3.8- — R. Wedekind und Co. Ger. Pat. 210,863, June 2, 1908. Addition to Ger. Pat. 202,398, May 6, 1903.

IZARIN-3-MONOSULPHONIC acid is converted into a mixture of the 3.5- and 3.8-disulphonic acids by treatment with fuming sulphuric acid in presence of mercury. The 3-sulphonic acid need not be isolated; thus, 100 parts of izarin are heated at 110° C. for ten hours with 500 parts of sulphuric acid (20 per cent. anhydride); ten parts of mercury are then added, and the mixture heated for a further ten hours. The product is dissolved in water, and precipitated by potassium chloride. The salts of the 3.8-disulphonic acid are much more soluble than those of the 3.5-disulphonic acid. The sulpho-group in the 3-position is removed from both acids by treatment with sulphuric acid.—T. F. B.

Aromatic acyl-p-diamines; Process for preparing — Kalle und Co. Ger. Pat. 210,886, Sept. 3, 1907. COMPOUNDS of the general composition,

where X is a halogen, alkyl, or alkyloxy group, are treated with sodium polysulphide, thus replacing the chlorine by the disulphide group, which is then reduced to the SH group by treatment with iron in presence of an acid; this also reduces the nitro group to an amino group. The resulting derivative of *o*-amino-*m*-acylaminothiophenol is now etherified in the usual manner, when an acyl-*p*-amine containing a thioalkyl group in an *o*-position to the amino-group is formed. These compounds are of value in the preparation of disazo and other dyestuffs.

—T. F. B.

Dyestuffs of the anthracene series and intermediate products; Manufacture of — O. Imray, London. From Farbwerke vorm. Meister, Lucius, und Brüning, Höchst on Maine, Germany. Eng. Pat. 15,355, July 20, 1908. SEE Ger. Pats. 205,149 and 209,321; this J., 1909, 134 and 650.—T. F. B.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

Bleaching powder solutions; Determination of the alkalinity of — K. J. P. Orton and W. J. Jones. Analyst, 1909, 34, 317—318.

A KNOWN volume of the bleaching powder solution (or a known weight of solid basic hypochlorite) is added to a measured volume of approximately N/10 hydrochloric acid contained in a Drechsel bubbler, shielded from light. A rapid current of air, freed from dust, is then drawn through the liquid for three-quarters of an hour, or until all free chlorine is expelled (the presence of the latter being indicated by its bleaching action upon a drop of 0.1 per cent. methyl orange solution), after which the excess of

acid is titrated with N/10 sodium carbonate. The titre of the bleaching powder solution with N/10 thiosulphate or arsenite gives directly the volume of N/10 acid reacting with the hypochlorite, the alkalinity of the solution being represented by the difference between this and the total volume of N/10 acid used up. The requirements for accuracy, all of which are fulfilled by the above method of procedure, are that the hypochlorous acid formed shall react completely with the hydrochloric acid; all the chlorine shall be evolved as gas, none being converted into hydrochloric acid; and the hydrochloric acid shall not react with chlorate at the dilutions used and at the ordinary temperature.—W. E. F. P.

PATENTS.

Artificial silk materials; Manufacture of — W. P. Dreaper, Felixstowe. Eng. Pat. 11,959, June 2, 1908.

IN composite artificial silk threads in fine counts where the thread is in a condition similar to that of "boiled-off" silk, difficulty is experienced in the weaving. To remedy this, the threads are dried at such a tension that in the final state of the yarn the filaments stick together as in "raw" silk. In order to improve the state of the thread, it may be dried out of a solution of soluble oil or other suitable colloid.—P. F. C.

Silk fibroin; Process for obtaining — C. R. Baumann and G. G. Diesser. First Addition, dated Dec. 2, 1908 (under Int. Conv., Sept. 15, 1908), to Fr. Pat. 396,305, Nov. 6, 1908 (this J., 1909, 597).

ALBUMINOID substances, in general, besides silk fibroin, are soluble in formic acid, and if the solutions be evaporated, pellicles are obtained which are quite insoluble in water. A better product is obtained if a small quantity of such substances as glycerin, gelatin, or tannin be added to the acid. This property of formic acid can be employed to manufacture artificial silk without using formaldehyde.

—P. F. C.

Amianthus [asbestos] fibres; Process of "hydrophilisation," steaming, and curling of — G. Capitain and N. Richard. Fr. Pat. 397,075, Dec. 3, 1908.

THE carded material is immersed in a boiling solution of sodium or potassium hydroxide (2—3 per cent.), then plunged into a 10 per cent. solution of bleaching powder for 30—40 minutes or exposed to ozone for 15 minutes. After a rinsing, firstly in dilute acid and afterwards in water, the material is dried in a stove at 120° C. and then carded again. In order to increase its absorptive power, the product is finally submitted to a succession of steamings, each steaming being followed by drying at 300° C.

—P. F. C.

Chrome colours; Dyeing with — R. B. Ransford, London. From L. Cassella und Co., Frankfurt-on-Maine, Germany. Eng. Pat. 22,097, Oct. 19, 1908.

IN dyeing wool with certain dyestuffs it is advantageous to add to the dye-bath a bichromate and an acid or an ammonium salt in place of the acid. It is found that an improved result may be obtained if the acid or ammonium salt be replaced by a salt of magnesium or of an alkaline-earth which will dissociate in the hot dye-bath into an acid and a base, the base forming a lake whilst the acid fixes the dyestuff. *Example.*—Charge the dye-bath with 2 per cent. of Anthracene Chromate Brown EB, 1 per cent. of sodium bichromate and 2.5 per cent. of magnesium sulphate on the weight of the goods. Enter the goods at 70°—80° C., raise in 15 minutes to the boil, boil for 1—1½ hours, then rinse and dry.—P. F. C.

Dyeing velvet or other pile fabrics; Process for — with powdered dyestuffs. J. M. Charcun. Fr. Pat. 396,996, Feb. 10, 1908.

THE fabric is passed with its face upwards underneath a shower of powdered dyestuff, the excess being kept back by a bar stretched across the material whilst the rest is distributed by means of moving and fixed brushes. The material is then led through another machine provided with beaters and brushes to ensure a perfectly even

distribution of the dyestuff, and is afterwards dyed by passing it over a moistening device consisting of a bar thickly wrapped round with flannel which dips into benzene. By capillarity, the benzene travels through the flannel on to the velvet, and there dissolves and fixes the dyestuff. The fabric is finally dried and finished.

—P. F. C.

Dyeing yarn in the hank; Process and apparatus for —.

E. Esser und Co., Textil-Maschinen- u. Tuchschneermesser-Fabr. Fr. Pat. 397,189, Dec. 8, 1908.

Each hank is hung over two rods which are arranged the one vertically above the other and are fixed in slots in a framework at such a distance apart, that the hanks are kept straight but are not stretched. When the framework, which is open at the top and the bottom, is quite full of yarn, it is lowered into a vat containing the dye-liquor. By means of a pump the dye-liquor is then circulated through the yarn along its length.—P. F. C.

Dyeing, bleaching and other similar treatments of textile substances; Apparatus having a circulating bath for —.

H. Schirp. Fr. Pat. 397,252, Nov. 30, 1908.

This apparatus consists of a rectangular vat divided by a partition into two compartments, one, which has an air-tight cover, being used as a dye-vat whilst the other is employed as a reservoir for the dye-liquor. The material to be treated is packed on a false floor, with which the dye-vat is provided, and pressed down by a perforated cover. By means of a circulating pump, and a delivery pipe which leads from the reservoir, and can be put in communication with either the upper or the lower part of the dye-vat, the dye-liquor can be pumped through the material in either direction by suitably adjusting the stop-cocks on the pipes which connect the two vats with one another and with the delivery pipe.—P. F. C.

Dyeing process. Farbenfabr. vorm. F. Bayer und Co.

Fr. Pat. 397,659, Dec. 19, 1908. Under Int. Conv., Jan. 7, 1908.

VEGETABLE fibres can be dyed in one bath by dyestuffs of the anthraquinone series in the following manner. For 50 kilos. of cotton, a bath containing 1200 litres of water, 5 kilos. of alizarine (20 per cent. paste), 30 grms. of common salt, 3 kilos. of aluminium sulphate and 4 litres of calcium acetate solution of 16° B. is prepared. The yarn, which has been oiled in the usual way, is entered into this bath, which is kept cold for 20 minutes and then heated in 45 minutes to the boil. After boiling for 30–60 minutes the yarn is withdrawn, washed, and finally soaped.—P. F. C.

Dyeing half-silk with sulphide dyestuffs in a single bath;

Process for —. Farbwerk Mühlheim vorm. A. Leonhardt und Co. Ger. Pat. 210,883, Aug. 26, 1908.

HALF-SILK fabrics can be evenly dyed with sulphide dyestuffs by adding "diastafor" to the bath and dyeing at a temperature of 50–90° C., according to the dyestuff used; black dyestuffs require a temperature of 80–90° C., others from 50–60° C. For example 10 grms. of "Pyrol Blue conc." 2 grms. of sodium carbonate, and 20 grms. of sodium sulphide are dissolved in each litre of water, 50 grms. of diastafor and finally 20 grms. of sodium sulphate are added, and the goods are dyed at 50–60° C. (Compare Eng. Pat. 13,948 of 1907; this J., 1908, 332.)

—T. F. B.

Dyeings on cotton; Production of fast yellowish-red to violet-red —. L. Cassella und Co. Ger. Pat. 211,029, March 12, 1908.

THE diazo dyestuffs obtained from *m*- or *p*-azoxyaniline (or a homologue) and 2,5-aminonaphthol-7-sulphonic acid, which may also be produced by alkaline reduction of the dyestuffs formed by combining *m*- or *p*-nitro-diazo compounds with the aminonaphtholsulphonic acid in acid solution, give orange to violet dyeings on unmordanted cotton, which are, however, of no value, owing to lack of fastness. If these dyeings are treated with diazocompounds, very fast yellow-red to violet-red dyeings are produced. The dyed fibre is treated with 0.5 to 3 per cent. of its weight

of the diazotised amine (according to the depth of shade), allowed to remain in the bath for $\frac{1}{2}$ hour, washed, and dried.—T. F. B.

Drying bobbins and cops; Process and apparatus for —.

H. L'Huillier. Fr. Pat. 397,108, Feb. 13, 1908.

THE bobbins are arranged inside a strongly built vat which is provided with an air-tight cover. The vat is then closed and air is forced into it under pressure, so that the wet bobbins become thoroughly impregnated with it. The air, impregnated with moisture, is then withdrawn by an aspirating device until a good vacuum is obtained. Warm air is next pumped into the vat and penetrates into the interior of the wet material and takes up the residual moisture so that on pumping out the hot moist air the bobbins are left quite dry.—P. F. C.

Fabrics; Method of treating — to render them adhesive.

F. J. Gleason, Assignor to Massachusetts Chemical Co., Walpole, Mass. U.S. Pat. 925,894, June 22, 1909.

ONE side of the fabric is treated with a composition containing gutta-percha and one or more substances (e.g., asphaltum and pontianac) capable of keeping the gutta-percha in a plastic state. The coating is then permitted to dry, and the plastic components removed by the action of a solvent (e.g., carbon tetrachloride).

—A. G. L.

Designs or ornamental and colour effects on textile materials;

Method of producing —. J. Rübner, Cheadle Hulme. Eng. Pat. 12,455, June 10, 1908.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Bauxite production of the United States. U.S. Geol. Survey, 1909. [T.R.]

THE production of bauxite in the United States in 1908 amounted to 52,167 long tons, valued at \$263,968, a decrease of 45,609 tons and of \$216,362 compared with the production of 1907. The average price of the material at the mines was about \$5.06 per long ton, an advance of \$0.15 over the price in 1907.

The States producing bauxite on a commercial scale are Alabama, Arkansas, Georgia, and Tennessee. As in past years, Arkansas leads in production with an output of considerably more than 60 per cent. of the total. The actual production of this State, however, fell off about 43 per cent., and that of Georgia and Tennessee also decreased; the production of Alabama increased.

Sodium sulphite, and its equilibrium with water. H.

Hartley and W. H. Barrett. Chem. Soc. Trans., 1909, 95, 1178–1185.

THE authors describe the preparation and properties of pure anhydrous sodium sulphite, its solubility in water, and the spontaneous crystallisation of supersaturated solutions. They show that the salt exists in two stable forms, Na_2SO_3 and $\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$, the transition temperature being 22° C. The decahydrate could not be isolated. The anhydrous salt crystallises in the hexagonal system, and the hydrated salt in the monoclinic system. Solubility and freezing point curves are given for both forms. Supersolubility curves are given which show that the hydrated salt has a metastable range of about 30°. There was no indication of the formation of any other hydrate.—A. H. C.

odium metasilicate; Binary systems of — with the metasilicates of lithium, magnesium, calcium, strontium, and barium; of lithium metasilicate with those of potassium, magnesium, calcium, strontium, and barium; and the three-component system, $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$. R. C. Wallace. *Z. anorg. Chem.*, 1909, 63, 1—48.

The author has investigated the two-component systems of the alkali metasilicates with those of the alkaline-earth metals, and the three-component system, $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$, by the method of thermal analysis, combined with microscopic examination. The melting is effected in carbon tubes. There is a great tendency for these silicates to solidify as glasses on cooling, instead of crystallising, but lithium silicate, Li_2SiO_3 , crystallises readily in thin leaflets which are, unlike the sodium compound, not hygroscopic. Sodium silicate (m.p.t., 118°C .) forms continuous series of mixed crystals with the silicates of strontium (m.p.t., 1529°C .), barium (m.p.t., 1490°C .), and lithium (m.p.t., 1168°C .); with calcium silicate (m.p.t., 1502°C .) there is a gap in the series of mixed crystals at 70—80 per cent. of calcium silicate, and a eutectic point occurs at 1140°C . with 70 per cent. of this compound; with magnesium silicate (m.p.t., 549°C .) the melt solidifies to a glass, when 20—80 per cent. of the magnesium compound is present. Potassium silicate forms mixed crystals with lithium silicate, containing 60—100 per cent. of the latter. With lithium and calcium silicates there is a gap in the series of mixed crystals at 25—84 per cent. and a eutectic point at 979°C . with 50 per cent. of calcium silicate; lithium and magnesium silicates show a gap at 50—75 per cent. and a eutectic point at 876°C . with 55 per cent. of magnesium silicate; lithium and barium silicates show a gap at 35—92 per cent. and a eutectic point at 880°C . with 78 per cent. of barium silicate; and lithium and strontium silicates show a gap at 22—92 per cent. and a eutectic point at 900°C . with 60 per cent. of strontium silicate. Tamman's idea as to the concentration of saturated mixed crystals of two metals, that the saturated mixed crystal of the component with higher melting point always contains more of the easily melting component, than the mixed crystal of this component contains of that with the higher melting point, only applies to a limited extent to the silicates. The molecular volumes of the mixed crystals of lithium silicate with calcium and barium silicates are of linear functions of the concentration; this is only the case with conglomerates consisting of the two saturated mixed crystals. Corundum forms mixed crystals with sodium oxide, sillimanite with silica and with alumina, epheline with silica, sodium aluminate, and alumina, and sodium silicate with silica and probably also with alumina. The crystallisation of albite and nepheline glass, under the influence of sodium tungstate at 950°C ., takes place only at the surface between the glass and sodium mineraliser (sodium tungstate), the power of spontaneous crystallisation being greatly increased, but the rate of crystallisation little altered.—F. Soxh.

magnesium oxychlorides; Contribution to the knowledge of —. H. Hof. *Chem.-Zeit.*, 1909, 33, 693—694.

In an earlier paper (*Chem.-Zeit.*, 1908, 993), the author described a magnesium oxychloride of the type, $[\text{Cl}_2, 5\text{MgO}]$, obtained by electrolysis of concentrated solutions of magnesium chloride (the mother liquors from the manufacture of potassium chloride), as prepared by the extraction of bromine. The compound can be obtained in a pure state, by electrolysis of a concentrated solution of magnesium chloride (using a diaphragm in the cell), until magnesium hydroxide appears in the other compartment. The filtered solution on standing for 24 hours deposits the oxychloride, which is drained and washed free from adhering magnesium chloride with absolute alcohol. Water partially decomposes the oxychloride, and is thus not admissible for washing the latter. On drying, a fine granular powder is obtained, not attacked by dry carbon dioxide and having the composition, $[\text{Cl}_2, 5\text{MgO}, 14\text{H}_2\text{O}]$. Although cold water only partially decomposes the oxychloride, the latter is completely decomposed by prolonged boiling with water, magnesium hydroxide being precipitated and magnesium chloride

passing into solution. On adding an excess of water to a solution of the oxychloride in magnesium chloride, complete decomposition ensues, with separation of magnesium hydroxide. This reaction is noteworthy, inasmuch as the precipitated magnesium hydroxide absorbs free bromine present in the waste liquors, and renders the latter harmless to ironwork.

On prolonged exposure of the finely powdered oxychloride to a stream of carbon dioxide, it is partially decomposed, with formation of magnesium carbonate. The action is very slow, and proportionately slower with atmospheric carbon dioxide. This reaction also holds good when the finely powdered artificial stones (prepared by the action of strong magnesium chloride solutions on calcined magnesia) are similarly treated. The limited stability of such stones, and the loss of the polish of their surfaces, is due to this gradual action of atmospheric carbon dioxide. The presence of carbon dioxide does not, however, prevent the formation of the oxychloride, since if a current of carbon dioxide be passed through the cathode portion of the electrolyte above mentioned, from the commencement of the electrolysis, the separation of magnesium hydroxide takes place in the same way as before. Only after the prolonged passage of carbon dioxide, will the filtered electrolyte deposit magnesium carbonate; so that in this case also, the decomposition takes place with extreme slowness.

The author assigns to the chief compound concerned in the composition of the hard masses or stones, obtained by the interaction of magnesium chloride solutions and magnesia, the formula, $\text{MgCl}_2, 5\text{MgO}, 13\text{H}_2\text{O}$, and points out that the latter formula was also assigned by Davis (*Chem. News*, 1872, 25, 258) to an oxychloride deposit formed in ammoniacal solutions of magnesium chloride.

—E. C. V-E.

Copper carbonates, and cupricarbonates. S. U. Pickering. *Chem. Soc. Proc.*, 1909, 25, 188.

BESIDES the mineral azurite, $3\text{CuO}, 2\text{CO}_2$, and the ordinary carbonate of copper, malachite, $2\text{CuO}, \text{CO}_2, \text{H}_2\text{O}$, the following carbonates have been isolated. $5\text{CuO}, 2\text{CO}_2$: a blue, bulky precipitate, obtained by the precipitation of copper salts by sodium carbonate. $5\text{CuO}, 3\text{CO}_2$: a light blue, stable precipitate, obtained by precipitation with sodium hydrogen carbonate. $8\text{CuO}, 3\text{CO}_2, 6\text{H}_2\text{O}$: a rather dark blue substance, obtained by the action of water on the double carbonate of copper and sodium.

All the basic carbonates are insoluble in water and in sodium carbonate solution, but they dissolve slightly in aqueous carbonic acid and in acid carbonates, a normal copper carbonate, or a double carbonate of copper and the alkali metal, being formed. The latter is obtained as a molecular compound in rather light blue crystals from such solutions, although in the solutions it is present in another form, as sodio-cupric carbonate, of the constitution: $\text{NaO.CO.OCuO.CO.NaO}$. In this compound the copper is electro-positive, but has a colour 30 times more intense than the copper in copper sulphate. When excess of sodium carbonate is added to it, the copper becomes electro-negative, and has a colour 80 times more intense than that in copper sulphate. The substance then present is an *a*-cupricarbonate, consisting of $\text{Na}_2\text{Cu}(\text{CO}_3)_2$ united with Na_2CO_3 , but in which the copper is joined to the carbon atoms, and is in a quadrivalent condition. It oxidises dextrose, and the constitution suggested represents the presence of a loosely combined oxygen atom explaining such a reaction. Excess of sodium hydroxide decomposes it, but a greater excess dissolves the precipitated basic carbonate to form a deep violet-blue solution of the β -cupricarbonate, which consists of $\text{Na}_2\text{Cu}(\text{CO}_3)_2$, united with 1 or 2 NaOH . This, too, oxidises dextrose, and also combines with cellulose. It is stable in presence of excess of alkali, whereas the *a*-compound gradually decomposes, either into the crystalline double salt or into malachite. The sodio-cupric carbonate decomposes in a similar manner.

PATENTS.

Nitric acid; Concentration of dilute — by distilling with sulphuric acid. C. Uebel. Ger. Pat. 210,803, June 12, 1904.

THE dilute nitric acid is first concentrated by distilling with sulphuric acid of medium strength, and the distillate is subsequently distilled with strong sulphuric acid at a lower temperature. The residual sulphuric acid from the second distillation is used over again in the first stage of the process. The nitric acid vapour from the second distillation may be passed through a dephlegmator kept at 85°–95° C. before being condensed. In this way nitric acid of high concentration (95 per cent. or more) is obtained, together with a certain quantity of dilute acid, which is treated again by distillation with sulphuric acid. The process may be applied to the spent mixed acid from nitration processes. The mixed acid is first distilled in a vessel connected with a dephlegmator and as much nitric acid as possible recovered in a highly concentrated form. The residue is then transferred to a second still and the remainder of the nitric acid distilled over into the first still, from which it is subsequently recovered, together with nitric acid from a further charge of the mixed acid, in a highly concentrated condition.—A. S.

Sodium cyanide; Manufacture of —. J. Tcherniac, Streatham Hill. Eng. Pat. 26,581, Dec. 8, 1908.

THE solutions of sodium cyanide, obtained by passing gases containing hydrocyanic acid into caustic soda solution, contain excess of caustic soda, sodium carbonate, and occasionally sodium sulphate. Hydrocyanic acid is first added to such solutions, in quantity sufficient to convert the hydroxide and carbonate into cyanide, and then sufficient lime is added to precipitate the carbonate; if sulphate be present, barium or strontium hydroxide may also be added. The solution is now filtered and evaporated at as low a temperature as possible (preferably *in vacuo*), filtered if necessary, and allowed to cool. The hydrated cyanide thus obtained is dehydrated over caustic soda *in vacuo*, or by passing air over it and then over the caustic soda, the concentrated solution of the latter formed being used for the first operation. The dry flakes of sodium cyanide are compressed, forming a tough, elastic mass. In order to avoid evaporation of the sodium cyanide solution, a concentrated (e.g., 30 per cent.) sodium hydroxide solution may be saturated with hydrocyanic acid, the solution being kept at a temperature of about 40° C.—T. F. B.

Carbon; Suspension of — in alkali metals, and process of making same. E. Weintraub. Assignor to General Electric Co., New York. U.S. Pat. 922,645, May 25, 1909.

POTASSIUM is capable of dissolving large quantities of carbon, and the solution is conveniently effected by means of the liquid alloy of potassium with about 5 per cent. of sodium, which quickly dissolves graphite at the ordinary temperature, the operation being carried out in a vacuum or in some inert gas. The suspension, which is claimed as new, may be put to a variety of uses and constitutes an intermediate product in a number of processes, e.g., the preparation of potassium cyanide by the absorption of nitrogen.—F. SOBX.

Sodium sulphide; [Manufacture of —.] E. H. Strickler, White Plains, N.Y., Assignor to General Electric Co., New York. U.S. Pat. 915,633, Mar. 16, 1909.

SODIUM sulphide is made in the form of flakes or laminae by causing the molten sulphide, concentrated to 60 per cent. or over, to be picked up in a thin film by a rotating drum; this is cooled internally and skims the surface of the material, which is thus rapidly cooled and solidified and may be continuously removed by a scraper. A uniform brick-red colour generally characterises the product, and it is, moreover, readily soluble and very pure, since the impurities in the crude sulphide settle to the bottom of the tank.—F. SOBX.

Tungstic anhydride; Process of purifying —. E. I. Beckwith, Schenectady, N.Y., Assignor to General Electric Co., New York. U.S. Pat. 926,084, June 2, 1909.

TUNGSTEN trioxide is treated with carbon tetrachloride vapour at a red heat. The resulting volatile chlorine compound is sublimed, condensed, and treated with *aqua regia* to produce tungstic acid, which is further purified by solution in ammonia and reprecipitation with dilute nitric acid.—A. G. L.

Nitrogen from the air; Process of, and apparatus for obtaining —. C. Blagburn, Antioch, Cal., U.S.A. Eng. Pat. 25,535, Nov. 26, 1908. Under Int. Conv. Nov. 27, 1907.

THE process consists in bringing a stream of air into contact with molten or burning sulphur, the amount of which is always in excess of that required to combine with all the oxygen in the air treated, conducting away the resulting gases, removing the excess of sulphur and the sulphur dioxide from them, and storing the residual nitrogen. The apparatus comprises a furnace of considerable area in proportion to its height, in which a large body of sulphur is exposed to oxidation by the whole of the air treated. Means are provided for supplying sulphur and air to the furnace, and the gases are drawn from it through a series of purifying chambers, in which first excess sulphur vapours are deposited, and then sulphur dioxide, ammonia, carbon dioxide, and moisture are successively removed. The current of air is maintained through the furnace and the purifying chambers, and the residual nitrogen forced into a storage vessel by a pump, placed at the end of the series of chambers. Piping and valves are provided so that the gases drawn from the furnace can be deprived of sulphur vapours and sulphur dioxide, and then discharged by the pump into the air, and not passed through the remaining purifying chambers and stored, until they are sufficiently free from oxygen. A heating chamber the bottom of which slopes from the inlet to the outlet of the furnace, is arranged across the entire width of the furnace, in order to preheat the air used in the process.—W. C. H.

Sulphur, etc., from furnace-gases; Process of obtaining —. F. R. Carpenter, Denver, Colo., Assignor to The American Iron and Steel Alloys Co., Colo. U.S. Pat. 925,751, June 22, 1909.

FURNACE gases are first freed from solid particles mechanically carried over, and are then passed through or over glowing carbon to reduce sulphur compounds, air being admitted from time to time to maintain the temperature of the carbon. The reduced gases are then further heated to decompose "subsidiary sulphides," and are then cooled so as to condense and separate the sulphur.—A. G. L.

ass plates; Process and apparatus for manufacturing —. P. T. Sievert, Dresden, Germany. Eng. Pat. 7823, Nov. 20, 1908. Under Int. Conv., Nov. 28, 1907. Addition to Eng. Pat. 25,042 of 1908 (this J., 1909, 601).

To avoid any slip of the insulating or "ironing" surfaces of the surfaces of the glass plates, which might occur with the use of endless bands, the ends of the bands are cured to rolls, arranged in pairs, and the bands are alternately wound on or unwound from each roll. A uniform space is maintained between the bands by using them to pass over fixed guides, which are adapted to act as pressure surfaces.—W. C. H.

Sheet-glass; Continuous apparatus for the manufacture of —. E. Rowart. Fr. Pat. 397,505, Dec. 15, 1908. Under Int. Conv., Dec. 16, 1907, and Jan. 24, 1908.

MOLTEN glass flows from a tank-furnace into a channel adding to a "siphon" (or rather, a U-shaped channel) terminating in a narrow orifice at a slightly lower level than the surface of the glass in the tank; the width of the orifice corresponds with the thickness of the sheet to be made. The "siphon" is completely enclosed in a heated chamber except at the orifice, where the glass emerges into a delivery chamber, which is divided into two (or more) compartments, the one nearest the orifice being kept at a lower temperature than the other. This division may be effected by placing two square hollow cast-iron pipes just above the orifice; the glass emerges between these pipes, which are suitably heated. The second compartment may be formed by the walls of the heating chamber which surround the "siphon" being brought down in the form of a wedge to meet the cast-iron pipes. Above this delivery chamber is placed an annealing chamber, containing drawing and forming mechanism, consisting essentially of two vertical endless bands between which the sheet of glass moves upwards. This annealing chamber is kept at a suitable temperature by means of ports delivering air and gas.—A. G. L.

Tank-furnace for glass-making, metallurgy, etc. L. Rembaux. Fr. Pat. 397,548, Dec. 17, 1908.

MOLTEN glass from the furnace-tank proper overflows into a receptacle placed close to the tank. From the top of this receptacle an inclined plane leads to a second receptacle, close to the top of which is constructed a channel leading to a table provided with a roller for making plate-glass. The level of the molten glass in the tank is such that the first receptacle is normally full; from this receptacle the glass is forced to flow down the inclined plane by lowering a piston which nearly fills it into the first receptacle; the second receptacle is caused to overflow in a similar manner by lowering a second piston into it. The two receptacles may be heated by hot gases from the furnace; or they may be provided with separate heating devices.—A. G. L.

Quartz, etc.] Refractory ceramic materials; Process and apparatus for fusing and refining — by means of an electric resistance furnace. A. Voelcker. Fr. Pat. 397,140, Dec. 7, 1908.

THE apparatus consists essentially of a resistance composed of three carbon electrodes, one of which is fixed inside the furnace, whilst the other two are placed on opposite sides of the furnace in contact with the intermediate electrode, and are advanced further into the furnace as the quartz or other material in contact with the intermediate electrode melts; the resistance of the latter is thus diminished, and the temperature increased, so as to refine the material

under treatment. Or else, the quartz, etc., is placed inside a vertical tube of carbon, which forms one electrode; and is surrounded by crushed carbon, etc., forming the heating resistance material, and enclosed in a furnace lined with carbon blocks forming the second electrode. The carbon tube is closed at the bottom by a removable carbon plug, and at the top by a plunger, also of carbon, which can be lowered into the tube when the material is melted. If the diameter of the plunger is nearly as great as the bore of the tube, the molten material is forced in a very thin layer against the walls of the tube as the plunger descends, and is thus exposed to intense heating. The plunger may be made hollow, and compressed air, etc., admitted through it, if desired. The carbon tube may also be horizontal, in which case the plunger employed is also horizontal.—A. G. L.

Glass; Process and apparatus for drawing —. J. H. Lubbers, Assignor to Window Glass Machine Co., Pittsburg, Pa. U.S. Pat. 926,501, June 29, 1909.

SEE Eng. Pat. 23,968 of 1908; this J., 1909, 425.—T. F. B.

Metallisation of vitreous ceramic surfaces. Q. Marino, Assignor to E. J. Richardson, London. U.S. Pat. 925,365, June 15, 1909.

SEE Eng. Pat. 17,743 of 1907; this J., 1909, 22.—T. F. B.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Wood; Preservation of —. F. Seidenschneur. Chem.-Zeit., 1909, 33, 701—702.

FROM his experiments the author concludes that it is not necessary that the tar-oils used for the preservation of wood (railway sleepers) should contain phenolic compounds. This is in agreement with work by Flüge and others, according to which phenol dissolved in alcohol or in oils has scarcely any antiseptic properties. Examination of sleepers which were in good condition after 16 years' service showed that only neutral heavy oils were left, although the oils used when the sleepers were put down must have contained a large proportion of phenols. About 0.8 kilo. of neutral oil per sleeper (2.7 m. long and 16—26 cm. thick) is shown to be necessary for preservation; the Prussian State railways require 7 kilos. per sleeper. Comparative experiments were also made with pure anthracene oil, ordinary commercial tar-oil, heavy Russian lubricating oil, and a mixture of 60 per cent. of a so-called "S-oil" with 40 per cent. of anthracene oil. This "S-oil" was obtained by heating (Russian) petroleum to 150° C., adding 2 per cent. of sulphur, and further heating to 280°, most of the sulphur added being evolved at 170°—210° C. as hydrogen sulphide; the distillate passing over at 210°—280° was returned to the residual oil. The "S-oil" is a clear liquid, completely soluble in chloroform, benzene and ether, but it cannot be emulsified alone with sodium resinate soap solution, although it readily forms an emulsion when mixed with anthracene oils. From the wood-preservation experiments made, it appears that pure neutral anthracene oil is a slightly better preservative than the commercial tar-oil which contains phenols, that the mixture of "S-oil" and anthracene oil is only 20 per cent. less efficient than the anthracene oil alone, and that the lubricating oil, like crude petroleum, has no preservative action whatever.—A. G. L.

Portland cement; the Le Chatelier test for soundness. A. C. Davis. Proc. Inst. Civil Eng., 1908—1909, 175. Part I, 12 pp.

THE author's experiments were made chiefly to test the statements that rotary kiln cements show an increased expansion when tested by the Le Chatelier method after aeration. He finds that this is not the case. Rotary kiln cements, tested when fresh, show a smaller expansion than fixed kiln cements, fresh; on aeration, the expansion of rotary kiln cements decreases slightly, or remains nearly constant, whilst that of fixed kiln cements usually decreases considerably. Occasionally, a cement is found in either

class, the expansion of which decreases at first on aëration, and then, on further aëration, rises again to the initial value, after which it falls again. In the author's opinion, the 5 mm. expansion allowed by the British Standard Specification is a much more stringent limit than the tensile tests imposed by the same Specification, and has the effect of excluding many sound fixed kiln cements which satisfy the tensile tests and are otherwise satisfactory.

A table showing the expansion of two cements, and also of their component parts, both fresh and after different periods of aëration, is given, from which the following figures are taken: *Rotary kiln cement*, fresh, 2.0 mm.; after 35 days, 2.0 mm.; residue on 180×180 mesh, 25.25 and 24.0; cement through 180×180 mesh, 4.5 and 3.0; grit from flourimeter, 38.75 and 36.0; flour, 2.25 and 2.0. *Fixed kiln cement*, 3.5 and 3.5; residue on 180×180 mesh, 23.75 and 23.0; cement through 180×180 mesh, 2.75 and 1.0; grit from flourimeter, 21.0 and 7.0; flour, 1.0 and 2.0.—A. G. L.

Lime in presence of silicic acid [in cements, mortars, etc.]; Volumetric determination of —. K. Balthasar. Chem.-Zeit., 1909, 33, 646—647.

0.7 GEM. of the substance (e.g., a cement) is decomposed by heating with concentrated hydrochloric acid in a small porcelain basin. The contents of the basin are then washed into a 350 c.c. Erlenmeyer flask with a narrow neck, at the lower end of which a mark has been made. The liquid (about 50—100 c.c.) is heated for about two minutes to drive off any dissolved carbon dioxide, and 50 c.c. of a mixture of strong ammonia, glacial acetic acid, and ammonium chloride, are added, and the liquid heated to boiling. [The ammoniacal solution is prepared by mixing 25 grms. of ammonium chloride and 100 c.c. of glacial acetic acid in a litre flask, and filling up to the mark with strong ammonia.] To the boiling liquid exactly 50 c.c. of $N/2$ oxalic acid are now added, and the flask is then cooled until it is just warm to the touch, and made up to the mark with distilled water. The contents of the flask are well stirred with a glass rod for about three minutes, and are then poured through a dry filter. The first few c.c. of the filtrate are usually cloudy and are set aside, the clear filtrate being collected separately. 50 c.c. of the clear filtrate are then titrated with $N/10$ permanganate, after the addition of about 5 c.c. of concentrated sulphuric acid and a few c.c. of manganous sulphate solution. The presence of the small amount of magnesia usually occurring in cements is without influence upon the accuracy of this process, since it is not sufficient to affect the solubility of the calcium oxalate, and is not itself precipitated as oxalate. The process is particularly suited to the needs of a cement works laboratory, where rapid estimations of lime are frequently very desirable.—E. W. L.

Magnesium oxychlorides. Hof. See VII.

PATENTS.

Tiles and the like; Machine for coating —. C. A. Allison, London. From The Ceramic Machinery Co., Hamilton, Ohio, U.S.A. Eng. Pat. 3139, Feb. 9, 1909.

THE tiles are fed by means of a travelling belt, on to a series of two or more coating rollers, rotating horizontally in a bath of coating material, maintained at constant level, then over a roller only thinly charged with the same material, for the purpose of producing a smooth surface, then over an air blast which partly dries the coating and blows off any superfluous material adhering to the rearward edge. If desired the rollers may be completely submerged so that the tiles are carried along with their under face in contact with the surface of the coating material. The tiles are then carried over two or more ever-changing mottling rolls, rotating in a bath of suitable material.—F. R.

Brick; Process of making —. O. S. Davis, Assignor to W. H. Spake and O. A. Lagman, Anaheim, Cal. U.S. Pat. 924,745, June 15, 1909.

BRICKS, blocks, etc., are formed and pressed, dried, without baking, to expel moisture, and immersed in a

bath of asphaltum heated to 212°—700° F. When the asphaltum has penetrated the articles to a depth of about $\frac{1}{2}$ in., the latter are removed and exposed to a gradually decreasing temperature, which at first is approximately the same as that of the bath, in order to cause the asphaltum to penetrate the articles still further.—A. G. L.

Wood for lumber; Art of treating —. W. A. Hall, New York, Assignor to American Mahogany Co., Maine. U.S. Pat. 924,770, June 15, 1909.

WOOD is impregnated with an alkaline solution of phlobaphenes, extracted from hemlock or other bark. The solution should contain an excess of alkali over that necessary to dissolve the phlobaphene extract.—A. G. L.

Drying process in tunnel dryers for plastic materials, wood, and other substances. H. Gahler. Ger. Pat. 210,636, June 21, 1908.

THE process is specially applicable to such materials as are liable to crack during drying. The air used as drying agent is divided into two currents, of which one moves in the opposite direction to the materials being dried in the first half of the dryer, whilst the other moves in the same direction as the materials in the second half. The currents of moist air are then united, passed through a condenser and a heater, and again divided and used as before.—A. S.

Stone [artificial] from ashes; Process for the manufacture of —. P. Ehestaedt. Ger. Pat. 210,540, Jan. 1, 1907.

THE ashes are moistened with a mixture of 1 part of sulphuric acid and 4 parts of water, pressed into bricks, tiles, etc., and dried.—A. S.

Concrete and lime-mortar; Process for the manufacture of waterproof —. P. Mecke. Ger. Pat. 210,541, Nov. 15, 1908. Addition to Ger. Pat. 200,968, Feb. 15, 1908.

THE basic calcium oleate prescribed in the main patent (this J., 1908, 1021) may be replaced by the corresponding barium or strontium compound, and the aluminium sulphate by magnesium sulphate.—A. S.

Wood; Process of impregnating —. J. Chateau and J. Merklen, Paris. U.S. Pat. 925,292, June 15, 1909.

SEE Addition of Oct. 29, 1907, to Fr. Pat. 375,859 of 1907; this J., 1908, 336.—T. F. B.

X.—METALS AND METALLURGY.

Graphite; Separation of — in white cast iron heated under pressure. G. Charpy. Compt. rend., 1909, 148, 1767—1769.

EXPERIMENTS are described in which alloys of iron and carbon, such as white cast iron and iron carbide, were heated under pressures reaching about 15,000 atmos. and at 600—1200° C. In all cases the free carbon, arising from decomposition of the carbide, was found to separate as graphite, the effect being most marked at high temperatures.—F. SODX.

Tungsten in tungsten steel; Determination of —. H. Bartsche. Oesterr. Chem.-Zeit., 1909, [2], 12, 114—115. Chem. Zentr., 1909, 1, 2017—2018.

FROM 1.5 to 2 grms. of the metal are dissolved by heating with a mixture of 40 c.c. of concentrated hydrochloric acid and 10 c.c. of concentrated nitric acid, the solution is concentrated to 10—15 c.c., then diluted with four to five times its bulk of water, cooled, and filtered. In the residue, which consists of tungstic acid and silica, the tungsten is determined either (1), gravimetrically, or (2), volumetrically. (1). The residue is washed with hot dilute hydrochloric acid until free from iron, and then treated on the filter with a hot solution of ammonium carbonate, which dissolves the tungstic acid. The ammoniacal solution is evaporated, and the residue ignited, finally over a blast-lamp, whereby tungstic acid

from iron and silica is obtained. (2). The residue of tungstic acid and silica is washed first with hot dilute hydrochloric acid, and then with hot water, to which 5 cent. of sodium nitrate has been added to prevent the formation of a colloidal solution of tungstic acid. It is then dissolved in a known quantity (about 30 c.c.) of 10 sodium hydroxide, and the filter washed with hot water. The tungstic acid readily dissolves, whereas the silica remains mostly on the filter. The excess of alkali in the solution is titrated with $N/10$ sulphuric acid. If nolphthalein be used as indicator, the end point is attained with the ratio, $2NaOH:WO_3$, whilst with methyl orange the ratio is $2NaOH:4WO_3$. The author's method gives higher, but it is claimed, more accurate results than other methods. In Lunge's method, for example, in which the metal is dissolved in dilute nitric acid, and the tungstic acid precipitated by heating with sulphuric acid, the author found that weighable quantities of tungstic acid remained in the acid solution. (See also this J. 1908, 230).—A. S.

d; Determination of — in tinned articles. F. Knöppfle. Z. Unters. Nahr.-und Genussm., 1909, 17, 70.

The determination of lead in tin alloys is generally effected by oxidising the metals with nitric acid and separating lead nitrate from the insoluble metastannic acid. If the alloy be rich in iron, the ferric nitrate causes some of the stannic acid to be dissolved, and this then contaminates the precipitate of lead sulphate obtained. The best method for the separation consists in treating 0.1 grm. of the alloy in a dish with nitric acid of sp. gr. 1.50—1.52, added slowly until about 1 c.c. of acid has been used for every 0.1 grm. of metal. The dish is then covered with a watch-glass and water is added drop by drop from a pipette until no more red fumes are evolved. When the reaction is finished, the excess of nitric acid is evaporated off on the water-bath to such a point that the residue still remains moist. A calculated quantity of a hot solution of disodium phosphate is then added, followed by 50 c.c. of hot water. The tin is thus separated as stannic phosphate and the lead is precipitated in the filtrate by the addition of sulphuric acid. Sometimes the iron separates during evaporation in the form of the oxide, which is not readily re-dissolved. In this case a few drops of nitric acid must be added to dissolve the ferric oxide; the same must also be done if the evaporation be carried too far.—J. F. B.

mercury; Determination of — in ores. E. Beyne. Bull. Soc. Chim. Belg., 1909, 23, 263.

The author finds that Eschka's method, depending on amalgamation with a gold crucible lid, affords results in excellent concordance with those obtained by weighing precipitated mercury sulphide on a tared filter.—J. F. B.

ides of nitrogen and their compounds with metals, etc. Bonjean. See XVIII.B.

termining niobium in presence of tantalum. Taylor. See XXIII.

mining of metal articles; Draft regulations for the —. Report to the Home Secretary. [T.R.]

REPORT (Cd. 4740, price 2½d.) has been issued by E. T. Lawes on the objections made to the draft Regulations for the tinning of metal articles (see this J., 1908, 24). A new set of draft Regulations is appended to the report, embodying the recommendations made in the report.

etal production of Mexico. Mining World, Chicago, July 3, 1909. [T.R.]

URING the last 31 years (1877—1908), the total gold production of Mexico was 334,228,518 pesos, and that of silver was 1,649,528,978 pesos, a total gold and silver production of 1,984,757,496 pesos. The industry has

enjoyed substantial growth each year, with but few decreases.

The following table gives the production of metals in Mexico for the fiscal year 1907—1908.

	Kilograms.	Value, Pesos.
Gold	28,572	38,006,661
Silver	2,153,014	85,446,504
Copper, metal	38,912,109	18,437,165
Copper ore	80,556,418	6,396,096
Lead, metal	104,031,217	5,343,225
Lead ore	26,312	1,316
Zinc ore	43,339,938	888,474
Antimony, metal	4,405,847	81,672,847
Antimony ore	364,284	22,000
Mercury	No export	—
Tin	4,291	6,000
Iron	24,659	2,710
Iron ore	29,021	725

These figures are based on the exportation statistics and, with the exception of mercury, represent fairly completely the metal production, as the local consumption is almost entirely supplied from outside as manufactured products.

The value of the mineral exports of Mexico for the last two fiscal years (1906—07 and 1907—08) is given in the table following:—

	1907—8. Pesos.	1906—7. Pesos.
Gold	31,921,019	23,873,713
Silver	93,034,750	99,861,790
Antimony	1,691,187	1,427,423
Copper	24,834,068	28,792,778
Marble in bulk	36,063	81,724
Plumbago	64,376	134,365
Lead	5,344,561	3,644,738
Zinc	888,484	2,010,408
Other mineral products	616,115	419,064
Total value	158,430,625 (£15,843,062)	160,246,004 (£16,024,600)

Note: Peso = 2s.

The aluminium industry. Mining World, Chicago, June 26, 1909. [T.R.]

THOUGH there may be some recovery from the present price of £65 per ton, aluminium will not again be sold at £150 per ton. This will tend to eliminate all the weaker works.

The French companies have the strongest position, while the Aluminium Co. of America also is believed to have accumulated large reserves. The large amount spent by the British Aluminium Company on new water power during the last three years has depleted its resources, and like the Neuhausen Co., it probably will have to turn to other manufactures in order to earn profits. None of the producing companies has published any official returns for the past year, and the heavy reduction in price has entirely stopped the three new works which were being erected by English companies, and has also curtailed the output at some of the older works. The output for the last 12 years, with the average price per ton, is given in the following table:—

	Estimated production.	Average price.
Year.	Tons.	£.
1897	3,327	155
1898	3,953	—
1899	5,459	148
1900	7,192	—
1901	7,420	—
1902	7,750	120
1903	8,102	120
1904	8,550	—
1905	9,000	150
1906	12,000	200
1907	19,000	167
1908	25,000	97

Unless some modification and cheapening of the method of production occur, aluminium cannot remain long at its present low value, for the bare cost of production is £61 per ton, while most works cannot produce it under £80, so that some recovery in value is probable. Any process which would enable bauxite or other unrefined aluminous earth to be used directly in the electrolytic bath would greatly reduce the cost.

PATENTS.

Furnaces; Crucible ——. for melting steel and other metals. W. Miller, Coventry, Eng. Pat. 12,531, June 11, 1908.

THE hot waste gases from the furnace escape through the flues J, K, and L, thus heating the air entering the regenerative flue, H, which may be provided with baffle-plates, R'. The heated air passes by means of *h* through perforations, G, in the flanges, F, of a water trough, E. The air then enters the furnace partly through the grate, C, and partly through *f* and M, and the ports, *f*² and N. The supplemental air supply, entering at N, serves to consume the combustible gases escaping from the furnace. —B. N.

Steels; Treatment of low-grade ——. The Pearlite Steel Co., Ltd., and A. C. J. Charlier, London. Eng. Pat. 13,120, June 19, 1908.

LOW-GRADE steel is heated in a closed furnace to above the recalescence point, and then plunged into a chilling bath supplied with hydrogen or which generates hydrogen when the hot metal is immersed. The hydrogen combines with the carbon and iron of the steel forming "hydro-carbide of iron." When all action has ceased, the steel is subjected to a soaking heat for some hours in order to drive off any excess of hydrogen.—F. R.

Steel from low-grade material; Process of producing high-grade ——. W. R. Palmer, Assignor to F. A. Wilmot, Bridgeport, Conn. U.S. Pats. 924,818 and 924,925, June 15, 1909.

OPEN-HEARTH steel is made by charging with low-grade material a primary furnace, which is worked at a temperature below ordinary steel-making temperatures. A second furnace, working at ordinary steel-making temperatures, is also charged with low grade material (scrap) and flux, and a portion of the charge from the primary furnace is transferred to the second furnace, in which the refining is completed. Sufficient of the charge is left in the primary furnace to form a molten bath for the reception

of fresh low grade material, to which is added slag from the second furnace; or else a portion of the charge the second furnace is returned to the primary furnace. The primary furnace may also be tapped into a ladle from which a portion of the charge is delivered to the secondary furnace, whilst the remainder is returned to the primary furnace.—A. G. L.

Iron ores; Process for briquetting finely divided spath or other ——. W. Schumacher. Fr. Pat. 397,31 Dec. 10, 1908.

FINELY divided iron carbonate in the form of spath iron ore or clay iron-stone, or manganese carbonate mixed with calcium hydroxide, and made into briquetts which are heated in the presence of water or water vapor in closed vessels or in the air. Other ores containing iron carbonate and blast-furnace dust may be mixed with finely powdered iron carbonate (spathic iron ore etc.), or manganese carbonate and calcium hydroxide and treated in a similar way.—O. F. H.

Zinc; Appliances to be used in the refining of ——. during extraction by distillation. The New Delaville Spoh Co., Ltd., Birmingham, and E. H. Shortman, Bloxwich. Eng. Pat. 16,956, July 29, 1908.

INSTEAD of the open ended cylinder containing coke or coal, which is placed at the junction of the retort at the condenser for the purpose of intercepting the low fumes (see Eng. Pat. 7223 of 1907; this J., 1908, 456) a special cylinder is used having the ends closed and having an opening on the upper side, close to each of the ends. The fumes from the retort are retarded by the tortuous passage and a more complete separation of the lead obtained.—F. R.

Fumes of spelter furnaces; Treating ——. H. E. Howland and G. Hadley, Birmingham, Eng. Pat. 19,384 Sept. 15, 1908.

IN place of the short plain tube employed for condensing the zinc fumes from furnaces of the Belgian type, a long cylinder is used, fitted with baffle-plates for retarding the fumes, and terminating in a cone having a small aperture. Practically all the zinc is condensed, rendering the issuing fumes innocuous. Self-closing vents are provided between the baffle-plates to minimise the effect of possible explosion.—F. R.

Complex sulphide and other ores; Reduction of ——. H. R. Angel, London. Eng. Pat. 19,882, Sept. 2 1908.

THE ore is roasted and mixed with 10–50 per cent of raw ore, such as plumbiferous concentrates. Carbonaceous matter equal to about 25 per cent. by weight of the mixture is added, together with 6 per cent. of zinc oxide. If iron is present, an equal weight of lime is substituted for the zinc oxide. The whole is well mixed in a granular condition, charged into an open hearth furnace and covered, to prevent loss of metal during reduction, with sodium sulphate equal to one-third the weight of the ore. After the charge has melted, it is well rabbled; the metals are reduced rapidly. Plumbiferous concentrates can be treated in this way without roasting or briquetting, if sodium carbonate and iron oxide are added to the charge. With some ores it is advantageous to add about 5 per cent. of sulphuric acid before charging into the furnace.—F. R.

Sulphide ores; Process of treating complex ——. G. Kingsley, Toronto, Canada, Assignor to A. E. Kingsley, Denver, Colo. U.S. Pat. 914,730, Mar. 9, 1909.

COMPLEX sulphide ores are treated with dilute nitric acid, containing 6½–7½ per cent. of nitric acid, at a temperature of 176° F. Lead sulphide is completely dissolved without the formation of any lead sulphate by acid of this strength at the temperature mentioned.—A. G. L.

Copper and silver; *Method of thionous precipitation of —*. G. C. Westby, Murray, Utah. U.S. Pat. 23,916, June 1, 1909.

SUBSTANCES containing iron in suitable form are treated with a solution of sulphur dioxide derived from smelter gases. A solution containing "thio salts of iron" is obtained, which is used to precipitate copper and silver from their solutions.—A. G. L.

Alloys; Process of manufacture of metallic —. D. Landenberger. Fr. Pat. 397,151, Dec. 7, 1908.

Metals of the iron group, such as chromium, iron, manganese, tungsten, vanadium, etc., are introduced into alloys, such as those of copper and zinc, by melting zinc with an equivalent quantity of the chloride of the metal to be added, and then adding the alloy so obtained to the molten copper. Or, the copper may be melted first, then the chloride added, and finally the zinc. Small quantities, say 2 per cent., of aluminium are added to assist in the reduction of the chloride.—O. F. H.

Cast or metallic alloys; Production of ingots of —. J. F. Monnot. Fr. Pat. 397,231, Oct. 31, 1908.

The metal is cast through a layer of flux, such as a mixture of borax, sodium-potassium silicate, and fluorspar in suitable proportions, with the object of giving a sound ingot free from flaws, blowholes, oxide, etc. Finely-divided aluminium may be mixed with the flux. It is claimed that the metals thus cast are free from gases and that the method is particularly suitable for the casting of composite ingots such as ingots of iron and copper.—O. F. H.

Alumina and corrosive gases; Process for the treatment of —. United States Smelting, Refining and Mining Co. Fr. Pat. 397,268, Dec. 9, 1908. Under Int. Conv., April 7, 1908.

The process is intended for the treatment of the fumes produced in the roasting, etc., of sulphide ores. Vapour of sulphuric or other corrosive acids, which would destroy the filtering medium in the condensing plant, is neutralised by introducing into the gas a substance, such as lime, zinc oxide, etc., which will neutralise the acid. The neutralising substances are introduced into the gas in a finely divided state, and all solid particles subsequently extracted the usual way.—O. F. H.

Aluminium; Process for the production of —. E. Viel. Fr. Pat. 397,399, Feb. 22, 1908.

Alumina is made for the use of an alkali or alkaline-earth metal in the nascent state as a reducing agent. A compound of aluminium, such as alumina, a double chloride of aluminium and sodium, or cryolite, is mixed with suitable quantities of an alkaline salt, such as sodium carbonate, charcoal, and treated in the electric furnace. Minerals, such as bauxite, may be treated with an alkaline salt in a reverberatory furnace for the production of an aluminate which is freed from impurities, and subsequently treated with charcoal in an electric furnace with the addition of cryolite or other flux.—O. F. H.

Alloys from their ores; Process for heating, melting and volatilising various materials, applied particularly to the extraction of —. W. G. Williams. Fr. Pat. 397,459, Nov. 14, 1908.

The ores are melted and their metallic contents volatilised by means of concentrated solar heat. In the apparatus described, the solar rays are collected by a number of parabolic mirrors, and concentrated in the interior of a crucible in which the ore is treated. Means are provided for the continuous charging of the crucible and for the condensation of the metallic vapours.—O. F. H.

Alloys and steel; Method of making —. A. J. Boulton, London. From J. T. Jones, Iron Mountain, Mich., U.S.A. Eng. Pat. 12,324, June 6, 1908.

Accumulator plates; New product and its process of preparation for the constitution of —. H. de Laminière and Soc. anon. des Accumulateurs de Laminière. Fr. Pat. 397,176, Dec. 8, 1908.

Oxides of lead, e.g., minium, litharge, or mixtures of these, are mixed with a solution in distilled water of sodium or potassium tartrate or the double sodium-potassium tartrate. The solvent is afterwards evaporated, and the resulting paste is used for the manufacture of plates, either with or without a support.—B. N.

Electrolysers for the production of pure hydrogen and oxygen. R. Eycken, C. Leroy, and R. Moritz. Fr. Pat. 397,319, Dec. 9, 1908.

The electrode plates are built up, with separating diaphragms of asbestos, in the form of a filter-press, suitable

openings, in the top of each plate, which communicate also with the electrolytic cells, fitting together to form two channels for the escape of the gases. All the joints are surrounded on the outside by the atmosphere, and as the gases are kept at a pressure above that of the atmosphere, it is impossible for them to become mixed. The electrodes and diaphragms are kept clean by making the first electrode hollow, and in the form of a large reservoir, in which the sediment accumulates and from which it may be removed from time to time. This reservoir is divided into two parts, into which the gases pass, through the electrolyte, the pressure being maintained constant, and the delivery of the gases regulated by two floats and balanced valves.—B. N.

PATENTS.

Furnaces; Electrical induction —. C. Grunwald, Bredene, Germany. Eng. Pat. 3599, Feb. 13, 1909. Under Int. Conv., May 7, 1908.

In electrical induction furnaces, owing to electro-dynamic effects which arise between the primary winding and the melting bath, the upper surface of the latter assumes an oblique position, resulting in oxidation of the metal and corrosion of the melting bath. The object of this invention is to obviate these disadvantages. Upon the part, *a*, of the transformer yoke, *A*, which is surrounded by the primary winding, *D*, there is arranged an auxiliary winding, *F*, the ends of which are connected to a second auxiliary winding, *F*, the number of turns in *F* being less than in *D*. The tension produced in *F* is in opposition to that in *D* and is less than this by an amount such that there is produced, in the auxiliary winding, *D*, a current strength sufficient to counter-balance the electro-dynamic effects

mentioned above, the winding, *F*, occupying such a position that it has no appreciable influence on the equilibrium of the melting bath.—B. N.

Furnaces; Electrical induction —. C. Grunwald, Bredene, Germany. Eng. Pat. 7396, March 27, 1909. Under Int. Conv., Aug. 15, 1908.

The central horizontal section of the fusion gutter, containing the metal forming the secondary of the inductive furnace, is in the form of a rhombus, and working openings are arranged at the corners of the fusion hearth forming the acute angles of the rhombus. By the aid of the openings, the entire upper surface of the fusion bath may be surveyed and manipulated.—B. N.

Furnace; Electric —. L. D. Farnsworth, Palo Alto and M. J. Bartell, San Francisco, Cal. U.S. Pat. 924,603, June 8, 1909.

THREE electrodes are arranged horizontally in the furnace overhanging and built permanently into the crucible the inner ends of the electrodes being wedge-shaped, so that the space between the ends is substantially Y-shaped. The electrodes and crucible are so constructed, that the current, in passing from one electrode to the other, will be distributed vertically through the slag, and horizontally through the molten metal in the crucible. A "supply chamber" is provided at one side of the crucible and in open connection with the latter, so that the molten metal will flow freely into it. Means are provided with the chamber for displacing the molten metal, thus raising the level of the metal in the crucible, and at the same time varying the depth of the slag between the electrode and the metal.—B. N.

Ores; Method of reducing —. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co. New York. U.S. Pat. 924,130, June 8, 1909.

ORES consisting of oxides of refractory metals are electrically smelted with boron, the latter being present in about the quantity necessary to combine with the oxygen of the ore, so as to give a product low in boron. A gas flux may be added to the charge. Ferro-boron may be used instead of boron, in which case an alloy of the refractory metal with iron is obtained.—A. G. L.

Metals from ores and other substances; Apparatus for recovering —. L. Dion, Assignor to The American Electro-Hermatic Co., New York. U.S. Pat. 925,621, June 22, 1909.

FUMES or gases from molten metals are passed through a chamber containing several groups of electrodes. Each group is composed of materials reacting with only one of the metals present in the gases; currents of electricity of different strength are supplied to the different groups of electrodes. The gases emerge into another chamber in which they are forced to pass through a filter.—A. G. L.

Tin; Method and apparatus for the recovery of pure — from tin-plate scrap and lead-tin alloy. A. Noda. Second Addition, dated Feb. 10, 1908, to Fr. Pat. 386,491, dated Feb. 10, 1908 (this J., 1908, 692 and 1212).

EACH tank is divided into compartments separated by porous walls, the same tanks being used for both solution and deposition of the tin. The scrap or alloy contained in baskets is cleaned and washed and then introduced into the outer compartments of the tanks which are filled with a dilute solution of sulphuric acid to which has been added a small amount of hydrochloric acid. On the passage of the current the tin is dissolved as chloride and at once converted into sulphate with regeneration of the hydrochloric acid which becomes available for the solution of more tin. When all the tin has been dissolved, the basket is removed, its place being taken by a fresh basket. A concentrated solution of tin sulphate is thus obtained which is then pumped into the central compartment where it is electrolysed, the tin being deposited on the cathodes from which it falls into a tray at the bottom of the central compartment.—O. F. H.

ring and cleaning of small [metal] objects; Process for the electrolytic —. A. Levy. First Addition, dated Oct. 19, 1908, to Fr. Pat. 394,120, Nov. 13, 1907 (this J., 1909, 249).

The application of the process is claimed to metallic objects of all kinds and sizes.—B. N.

Metals; Electrolytic process for the extraction of — from their ores, and the treatment of waste copper. Soc. Française Electrolytique. Fr. Pat. 397,482, Feb. 25, 1908.

Hydrogen peroxide is added, either in bulk at the commencement or in progressive portions during the operation, to the electrolytic bath, with the object of redissolving the copper in the electrolyte of sulphuric acid, whilst preventing the solution of foreign metals. Substances or mixtures of substances, which will produce hydrogen peroxide, may be employed, e.g., peroxides, carbonates or perborates of alkali or alkaline-earth metals in the presence of hydrochloric, hydrofluoric, sulphuric, phosphoric, carbonic, or other acids.—B. N.

Copper and analogous metals; Electrolytic process of extraction of — from their ores or alloys. Soc. Française Electrolytique. Fr. Pat. 397,483, Feb. 25, 1908.

Sulphuric, or monopersulphuric, acid is added to the electrolyte, either in bulk at the commencement or in progressive small portions, thus providing a permanent source of chemically active oxygen for the rapid solution of the copper, and at the same time maintaining the composition of the bath constant by regeneration of the electrolyte. The acid may be generated in the bath, by preliminary operations, e.g., by dissolving in water the product of the action of the electric discharge on a mixture of sulphur dioxide and oxygen; by the electrolysis of a solution of sulphuric acid; or by the solution of persulphate in cooled sulphuric acid.—B. N.

German silver and other copper-nickel alloys; Process for the preparation of — from mixtures of metals containing iron. Elektrostahl Ges.m.b.H. Ger. Pat. 10,550, Sept. 6, 1907.

The metal mixture containing iron is melted in an electric furnace of the Kjellin or Héroult type, or it is first melted and then run into the electric furnace. Compressed air or other oxidising gas is then blown into the bath, after addition of a flux if necessary. The iron or iron and salt pass into the slag, and after removing the latter, the necessary additions of metal are made to the residual copper-nickel alloy, according to the product desired.

—A. S.

German silver or other copper-nickel alloys; Process for the preparation of — from mixtures of metals containing iron. Elektrostahl Ges.m.b.H. Ger. Pat. 11,215, Sept. 6, 1907. Addition to Ger. Pat. 210,550, Sept. 6, 1907.

The oxidation of the iron is effected by means of oxides of nickel or copper, instead of by oxidising gases as in the main patent (see preceding abstract).—A. S.

Metals from their ores; Electric furnace for the continuous extraction of —. E. F. Côte and P. R. Pierron, Lyons, France. Eng. Pat. 18,653, Sept. 5, 1908. Under Int. Conv., Feb. 12, 1908. Addition to Eng. Pat. 5100, March 2, 1907.

Addition of Feb. 12, 1908, to Fr. Pat. 385,018 of 1907; this J., 1908, 864.—T. F. B.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Cottonseed oil; Unsaponifiable constituents of —. H. Matthes and W. Heintz. Arch. Pharm., 1909, 247, 61—175.

The refined cottonseed oil examined by the authors yielded 0.71 per cent. of unsaponifiable matter with an

iodine value of 77. This did not give Beechi's reaction, and was quite free from sulphur. In the authors' opinion the 0.5 per cent. of sulphur found by Wagner and Clematis (this J., 1909, 372) in the unsaponifiable matter of cottonseed oil was derived from impurities. On distillation of the last portion of the ether and alcohol used in the separation of the unsaponifiable constituents, a characteristic aromatic odour recalling that of peppermint was observed. This was attributed to the formation of secondary products through the action of the alcoholic potassium hydroxide upon the phytosterol. A similar decomposition was effected by the long-continued action of alcoholic alkali solution upon purified phytosterol from Calabar beans. The unsaponifiable matter from cottonseed oil could be separated by treatment with chilled petroleum spirit into a solid and a liquid portion. The solid crystalline portion consisted of (a), a phytosterol (m. pt. 139° C.) which was levo-rotatory and contained one double linkage; (b), a saturated substance melting at 81° to 82° C.; and (c), a dextro-rotatory unsaturated substance containing oxygen (m. pt., not sharp, 172° C.). The liquid portion was separated by distillation under reduced pressure into several unsaturated substances. These were yellow or yellowish-brown oils containing oxygen. The authors' results confirm the experience of Windaus and Welsch (this J., 1909, 316) that many of the new phytosterols recently described are in reality mixtures of phytosterols already known.—C. A. M.

Fatty acids in soap; Determination of —. M. Dominikiewicz. Chem.-Zeit., 1909, 33, 728.

The apparatus (see Fig.) used in the author's method of determining the total fatty acids in soap is constructed on the principle of the butyrometer for the determination of fat in milk. It consists of a tube the wider end of which is closed by means of a rubber cork, whilst the narrower part, on which is the scale, is closed by means of a metal cap, which can be screwed down. Each division of the scale corresponds to 0.01 c.c. In making a determination, from 40 to 60 grms. of the soap are dissolved in water, and the solution diluted to 1 litre. Ten c.c. of hydrochloric acid and 10 c.c. of the soap solution are introduced into the tube, which is then lightly shaken, with the wider part downwards. It is next placed for 5 minutes in a flask of boiling water, after which it is whirled for 5 minutes in a centrifugal machine. By unscrewing the metal cap and pressing the rubber cork further into the other end, the separated layer of fat is brought within the limits of the scale. The apparatus is now replaced in the flask of boiling water, and the amount of fatty acids read upon the scale at 99° C. The sp. gr. of the fatty acids should be determined, and the necessary correction applied. The results obtained by this method are shown by test experiments to be in close agreement with those given by the usual gravimetric method.—C. A. M.

Stearolic and behenolic acids; Glycerides of —. H. Quensell. Ber., 1909, 42, 2440—2452.

SYNTHETICAL glycerides were prepared from stearolic and behenolic acids by various methods, including Scheij's modification of Berthelot's process (heating the equivalent proportions of acid and glycerol in a sealed tube containing carbon dioxide) and the methods of Guth (this J., 1903, 427) and of Kraft (Ber., 1903, 36, 4311), in which the sodium salts of the acids are heated with chloro- or bromohydrins. The resulting products were readily purified by crystallisation from alcohol. They absorbed one mol. of chlorine or bromine rapidly, but long continued action under the influence of light was required for the absorption of two mols. On the other hand, not more than one mol. of iodine or of iodine chloride (from Hübl's solution) could be made to combine with the

triple linkage in these acids or their glycerides. The following compounds were prepared:— α -monostearolin, $(\text{CH}_2\text{O.CO.C}_{17}\text{H}_{33})(\text{CH}_2\text{OH})(\text{CH}_2\text{OH})$, crystallising in white plates of m. pt. 40.5°C ; α -distearolin melting at 38.5°C ; β -distearolin (m. pt. 49°C); tristearolin (m. pt. 29°C); epistearolhydrin (m. pt. 36°C). The corresponding compounds of behenic acid were also prepared. They had higher m. pts. and crystallised better than the glycerides of stearic acid. Thus tribehenolin $(\text{CH}_2\text{O.CO.C}_{21}\text{H}_{41})(\text{CH}_2\text{OH})(\text{CH}_2\text{OH})$ (m. pt. 41°C) crystallised in brilliant white plates melting at 41°C . Various halogen compounds of the glycerides of stearic acid were prepared. Most of them were heavy oils which did not solidify even when cooled to a low temperature. —C. A. M.

Juniperic and sabinic acids. J. Bougault and L. Boudier. J. Pharm. Chim., 1909, 30, 10—16. (See also this J., 1909, 29.)

JUNIPERIC acid, $\text{C}_{16}\text{H}_{32}\text{O}_4$, was present in all the "waxes" from the *Coniferae* examined by the authors, but sabinic acid, $\text{C}_{12}\text{H}_{24}\text{O}_4$, was only found in the wax of *Juniperus sabina*. For the separation of both acids those portions of the wax of *J. sabina* melting at about 80°C . were mainly used. The mixed fatty acids from the wax were separated into two groups by treatment of their sodium salts with a 4 per cent. solution of sodium chloride. The insoluble salts consisted of those of juniperic acid and some other acids not yet obtained in a pure state, whilst the soluble portion consisted almost exclusively of the salt of sabinic acid. The juniperic acid was then isolated by recrystallising the liberated acids of the insoluble salts from a mixture of petroleum spirit and ether until a substance of constant m. pt. was obtained. *Juniperic acid*, as thus prepared, melted at 95°C , but after resolidification its m. pt. was lowered to 83°C . Its molecular weight, elementary composition and saponification value of its acetyl derivative agreed with the formula, $\text{C}_{16}\text{H}_{32}(\text{OH})\text{COOH}$, of a hydroxy-palmitic acid. It was slightly soluble in boiling water, fairly soluble in acetone (2 to 2.5 grms. per 100 c.c.), and in hot ether and petroleum spirit. All its salts, including the alkali salts, were insoluble in water, but the sodium, potassium, and ammonium salts could be crystallised from 90 per cent. alcohol. The acetyl derivative melted at 63°C . and was more soluble than the original acid in ether and petroleum spirit. It could be crystallised in fine spangles from 60 per cent. alcohol. *Sabinic acid* melted at 84°C . and from its analytical values it was concluded to have the composition of a hydroxylauric acid, $\text{C}_{11}\text{H}_{22}(\text{OH})\text{COOH}$. It was much more soluble in alcohol and acetone (10 grms. per 100 c.c. at 20°C .) than juniperic acid, but was only sparingly soluble in cold petroleum spirit, which was therefore used for its purification. A solution of its potassium salt yielded a crystalline precipitate on the addition of magnesium sulphate and a gelatinous precipitate with calcium sulphate. The silver, barium, and lead salts were white amorphous precipitates. The acetyl derivate melted at 43°C . and was very soluble in ether, petroleum spirit, and 60 per cent. or 90 per cent. alcohol. —C. A. M.

PATENTS.

Oils and all other similar products; Centrifugal filtering apparatus for the simultaneous extraction and filtration of —. H. Morel-Révoil. Fr. Pat. 397,203, Dec. 8, 1908.

The crushed olives or other material are placed in a rotatable inner vessel, the vertical wall of which is perforated and surrounded by the filtering material. The oil is thus driven through the filter into the external chamber. —C. A. M.

Soap and similar articles; Apparatus for the manufacture of —. G. M. L. Moore-Irvine. Newry, Ireland. Eng. Pat. 11,623, July 10, 1908.

The liquid soap or other material (jelly, butter, etc.), is introduced by means of gravitation, or otherwise, into a receiver, the bottom of which opens into a number of tubes surrounded by a refrigerating chamber, through the

lower end of which they project. A piston or plunger is driven into the receiver, and when driven by suitable mechanism, forces the soap into the tubes, where it is cooled and compressed into solid bars. The apparatus may also be used as a horizontal apparatus, and appliances may be fixed at the outlets of the tubes to cut the bars into suitable lengths. —C. A. M.

Soap frames. A. G. Bloxam, London. From the F. A. Jacobi, Darmstadt, Germany. Eng. Pat. 21,801, Oct. 15, 1908. Addition to Eng. Pat. 18,253 of 1907 (this J., 1908, 693).

A SPECIAL vent for the escape of the air is arranged on the edge of the side of the frame for the purpose claimed in Eng. Pat. 18,253 of 1907. This vent may be formed by fixing a grooved metal plate to the edge of the side, so that the concave surface of the groove is turned towards the cooling plate. —C. A. M.

Detergent compound. A. Kayser, Buffalo, N.Y., Assignor to The Electric Smelting and Aluminium Co., Lockport, N.Y. U.S. Pat. 923,850, June 8, 1909.

ALUMINA (one molecular proportion) is mixed with silicic acid (2 to 8 molecular proportions) and the oxide of an alkali metal, e.g. sodium oxide (4 to 6 molecular proportion) to form a hydrated detergent composition which is stated to contain the respective elements in the molecular proportions of Al_2 , Si_2 , Na_4 and O_{12} . —C. A. M.

Detergent. A. Kayser, Buffalo, Assignor to The Electric Smelting and Aluminium Co., Lockport, N.Y. U.S. Pat. 924,792, June 15, 1909.

CLAIM is made for a detergent, consisting of a soap, which are intermixed, one molecular proportion of alumina, 2—8 molecular proportions of silica, and 4 molecular proportions of sodium oxide or other alkali metal oxide. —F. SODS.

Detergents and other chemical products; Manufacture of —. N. Reif. Fr. Pat. 397,412, Dec. 14, 1908. Under Int. Conv., Dec. 14, 1907.

EQUIVALENT quantities of substances which intervene immediately to form solid products (e.g. sulphur chlorides and an oil, sodium carbonate and soap, etc.) are brought together in a continuous operation, mixed, and discharged from the apparatus by a rotary motion which leaves the final product in a fine granular or flocculent state. Or the pulverisation may be effected by means of a helicoidal device surrounded by a cover which may be turned so as to regulate the size of the outlet orifice. Other modifications of the apparatus are also claimed. —C. A. M.

Extracting grease and oil from garbage. U.S. Pats. 925,910 and 925,971. See XVIII. B.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(B).—RESINS, VARNISHES.

Acaroid resin; Red —. L. E. Andés, Chem. R. Fett-u. Harz-Ind., 1909, 16, 160—161.

OF the various species of *Xanthorrhoea*, the *X. Drummondii* (W. Australia) is reputed to afford most resin, a single tree yielding an average of 23 kilos. of a yellow resin. Attempts have been made to produce an illuminating gas from a mixture of equal parts of the resin and leaves of the plant. The gas has the sp. gr. 0.888, and possesses a greater illuminating power than coal gas; tar and coke are also produced. *X. totiana* (S. Australia and Kangaroo Island) furnishes a ligneous, vesiculated, readily friable and odourless resin. The mass is dark red; the powder is yellowish and imparts a blood red color to hot water. Petroleum ether extracts 1 per cent. of a colourless odourless resin; strong alcohol dissolves it entirely, forming a fiery red solution, which deposits crystals of benzoic acid on evaporation. *X. haasii* (N.S.W. and Queensland) produces a resin of sweet

our, resembling that of benzoin: it is readily friable, powder resembling gamboge and undergoing change colour when exposed to light. It melts in boiling water, during the latter turbid and yellow. Petroleum ether extracts 1 per cent. of a pleasant-smelling substance; alcohol dissolves 94 per cent., and the solution affords very crystals of benzoic acid on evaporation. The refined resin melts at 97.5° C. Another sample, showing lower melting point, yielded to petroleum ether, 2 per cent. of a faintly coloured viscous body, probably composed of essential oils and resin. *X. arborea* (N.S.W. and New Zealand) furnishes compact pieces mixed with leaves; colour of the product varies from purple brown to mine red. It forms a readily friable powder, of the colour of raw sienna, and tastes like benzoin. Petroleum ether extracts 8 per cent.; alcohol, 92 per cent. of this in; the alcoholic extract deposits crystals of benzoic acid, but in lesser quantity than the other *Xanthorrhoea* ins. *X. australis* (Tasmania and Victoria) affords regular shaped spheroidal masses of resin of a dark colour. The resin is readily friable. In the fused state, it resembles dragon's blood. Its alcoholic solutions are clearer than those of the other species of *Xanthorrhoea* ins. It occurs in all the species of *Eucalyptus*, with exception of *E. amygdalina*. It is only partially soluble in ether, and insoluble in oil of turpentine. Hesse recommended melting acroind resins to free them from woody fibre. The author has found, however, that on melting the resins, there is a troublesome frothing, and unpleasant smelling decomposition products are evolved. Moreover the properties of the resin are materially altered, and this treatment must be regarded unsuitable.—E. C. V-E.

PATENTS.

Terpentine oil substitutes; Preparation of — P. Pellaitz. Addition, dated Dec. 8, 1908, to Fr. Pat. 394,467, Sep. 19, 1908. (See Ger. Pat. 202,254; this J., 1908, 1212.)

The process may be carried out without the aid of pressure vaporising the mixture of terpenes and acetic acid "resin acid," and bringing it into direct contact with one or ozonised air.—C. A. M.

Enols and aldehydes; Process for hardening products of the condensation of — Knoll und Co. Fr. Pat. 397,051, Dec. 3, 1908. Under Int. Conv., July 3, and Oct. 20, 1908.

Acid, which may be diluted with a liquid other than water, is added to the products of the condensation of enols and aldehydes prior to their hardening, with the object of accelerating the process. Or the products may be treated with substances (such as esters of sulphuric acid, or chlorides of organic or inorganic acids) which readily yield a free acid, or with acid salts in solid form solution.—C. A. M.

Rubber; Determination of — in hot-vulcanised rubber goods. G. Hübener. Chem.-Zeit., 1909, 33, 648—649 and 662—663. (See also this J., 1909, 251, 720).

Axelrod's process (this J., 1907, 1058) the precipitate obtained by the action of bromine on a solution of vulcanised rubber in petroleum consists of a mixture of the monosulphide, $C_{16}H_{16}Br_2S$, and the tetrabromide, $C_{16}H_{16}Br_4$, of caoutchouc, any disulphide, $C_{16}H_{16}S_2$, present remaining in solution. Hence the same factor, 4, may not be applicable in all cases to the estimation of the rubber-content. The method now described is designed to overcome that difficulty. It seems almost possible to devise a single process that shall be suited to every case, on account of the very varied nature of rubber mixings, but the following can be employed in most instances for the direct estimation of rubber:—5 grms. of the finely rasped sample are extracted with acetone for from 4 to 6 hours: in cases where resins soluble in acetone are present, as in some ebonite mixings, this extraction must be followed by an extraction with dichlorhydrin. The extracted sample is dried at

60° C. and weighed, 0.2 grm. (or more in the case of mixings with low rubber content) of the dry, extracted sample, is placed in a flask in contact with 100 c.c. of distilled water and 5 to 10 c.c. of bromine, and the flask is warmed gently on a sand-bath until the reaction is complete and the greater part of the excess of bromine is volatilised. The excess of bromine is then completely driven off by heating more strongly. The precipitate is filtered off (Schleicher and Schüll's "White band" filter No. 590 is recommended for this purpose), and washed with hot water. The precipitate and filter are transferred to a 400 c.c. Erlenmeyer flask, excess of $N/10$ silver nitrate (about 20 c.c.) is added, together with about 20 c.c. of concentrated nitric acid and the liquid is heated until nitric acid fumes are given off and the liquid is reduced to about 15 c.c. in volume. The liquid is diluted with water and cooled, 5 c.c. of a cold saturated solution of iron alum are added, and the excess of silver nitrate titrated with $N/10$ ammonium thiocyanate. From the amount of silver used, the amount of rubber present in the precipitate, potentially as tetrabromide, is calculated. The remaining portion of the rubber is estimated from the combined sulphur, the latter being taken as the difference between the amounts of free sulphur and total sulphur; the calculation is based on the assumption that this portion of the rubber is potentially present as disulphide, $C_{16}H_{16}S_2$ (see this J., 1909, 252). Total sulphur is estimated in the manner previously described (loc. cit.). Free sulphur is estimated in 0.2 grm. (or more) of the original substance by oxidation with bromine water, filtration from the precipitate formed, acidification with hydrochloric acid and precipitation with barium chloride. If, in the ash, metals are found to be present which form sparingly soluble sulphates, they must be estimated, and the sulphur added to the free sulphur previously found. By making use of the fact that the tetrabromide, $C_{16}H_{16}Br_4$, is soluble in carbon bisulphide, it is possible to differentiate between "free rubber," $C_{16}H_{16}$, unsaturated sulphide, $C_{16}H_{16}S$; and saturated disulphide, $C_{16}H_{16}S_2$ present in the vulcanised rubber. Results obtained with a number of different soft and hard rubbers are given.—E. W. L.

Vermilion and "golden sulphide" [of antimony] in rubber goods; Determination of — J. Rothe. Chem.-Zeit., 1909, 33, 679. (See also this J., 1909, 614.)

The coarsely-divided sample is heated in a spacious round-bottomed flask with a mixture of 10 to 20 c.c. of nitric acid (sp. gr. 1.48) and 2 c.c. of concentrated sulphuric acid for every 1 grm. of the sample taken, for one to two hours, the temperature being regulated so as to ensure a regular and steady evolution of gases from the liquid. Finally, the temperature is raised until all the nitric acid is driven off, and sulphuric anhydride fumes are evolved. 5 to 10 c.c. of concentrated nitric acid are then added, and the liquid kept gently boiling until it becomes clear, after which the flask is heated until the sulphuric acid boils and fumes. Should the liquid darken in colour again, a further 5 c.c. of nitric acid must be added and the process repeated until the liquid remains clear. Traces of nitrogen oxides which remain in the liquid even after the sulphuric acid has been brought to the boiling point, may be removed by diluting the acid liquid with water, and boiling it for a short time. The estimations are from this stage carried out in the ordinary way, the organic matter having been completely destroyed without loss of volatile metals.—E. W. L.

PATENTS.

Hard rubber or ebonite; Manufacture of — T. Gare, New Brighton. Eng. Pat. 4484, Feb. 28, 1908.

CLAIM is made for a process based on the same principle as that of Eng. Pat. 12,354 of 1906 (this J., 1907, 339). Old or waste vulcanised rubber, preferably reduced to powder, is mixed with a suitable proportion of sulphur or other vulcanising agent (say 15 per cent.), and pressed to the desired density in a mould of the required shape, air being thereby expelled. The mould containing the compressed mixture is then locked and heated for a suitable length of time, and subsequently cooled.—C. A. M.

Caoutchouc, leather, and analogous products; Method and composition for joining, cementing and hardening — C. Coquerelle. Fr. Pat. 397,561, Feb. 27, 1908.

THE substance is treated in the cold with a composition containing several constituents, such as phosphorus and its derivatives, capable of adhering to caoutchouc or leather and of hardening under the influence of heat. A suitable preparation claimed consists of:—Phosphoric acid, 4.97; lime, 5.18; alumina, 61.90; iron oxide, 4.39; and lead oxide, 23.36 per cent.—C. A. M.

Gelatoid thermoplastic compound. B. B. Goldsmith, N. York. U.S. Pat. 925,328, June 15, 1909.

THE composition consists of an intimate mixture of β -naphthol with a gelatoid. The mixture, after thorough incorporating, is subjected to heat and pressure.

—G. W. McD

Joining, cementing, and hardening caoutchouc, leather, Fr. Pat. 397,561. See XIII C.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Hide powder; Rapid method of determining the acidity of — A. T. Hough. Collegium, 1909, 218—219.

THE method proposed by the author consists in weighing out the equivalent of 6.5 grms. of dry hide powder, adding about 100 c.c. of boiling distilled water, stirring for two or three minutes till the powder is thoroughly soaked and partly gelatinised, and then titrating while hot with N 10 sodium hydroxide solution, using a liberal amount of phenolphthalein (3—4 c.c.) as indicator. It is sometimes advantageous to boil the hide powder for a short time, as within limits, the more gelatinisation which takes place, the better the reaction. The reaction is fairly sharp, giving a permanent pink in two or three minutes, and it is said that results are obtained by the method, closely agreeing with those found by the official method of the Int. Assoc. Leather Trades Chemists.—S. H.

Ellagic acid; Artificial preparation and constitution of — P. Sisley. Bull. Soc. Chim., 1909, 5, 727—730.

PURE tannin prepared from Chinese extract of galls can be converted into ellagic acid by oxidation. 170 grms. of tannin are dissolved in 2½ litres of alcohol of 40°, and 150 c.c. of potassium hydroxide of 30° B. are then added. For each molecule of tannin there should be present two molecules of alkali. After exposure to the air for 5 days, there is an abundant separation of crystals of potassium ellagate. The ellagic acid obtained from this salt corresponds in its properties with the natural acid. The author considers that the production of ellagic acid by this reaction confirms the constitution of the acid as determined by Graebe (see Perkin and Nierenstein, this J., 1905, 1087). 45 grms. of tannin when hydrolysed by sodium hydroxide yielded 52 grms. of crystallised gallic acid, thus showing that tannin cannot be a glucoside.

—F. SUDN.

PATENTS.

Tanning extracts; Method of obtaining decolorised — E. W. Tillberg. Fr. Pat. 395,499, Oct. 20, 1908. Under Int. Conv., April 27, 1908.

MILK, preferably skimmed, or butter-milk, is added to the tanning extract and the mixture heated above 70° C. The albumin of the milk is thus coagulated, and in settling carries down the insoluble matter and part of the colouring matter of the extract. The clear liquor may be separated either by decantation or filtration.—S. H.

Tannage; Method of — of ungrained hides [sole leather]. Soc. Anon. des Mat. Tannantes et Colorantes. Fr. Pat. 396,025, Jan. 13, 1908.

THE raw hide is first swollen in a bath of formaldehyde and whilst still in a swollen state is given a first tannage in a drum with tanning extract. The hides are removed, dried completely, and then given a second tannage in the drum.—S. H.

Artificial leather; Production of — H. W. Lake, London. From Fiber Products Co., New York. Eng. Pat. 4130, Feb. 19, 1909.

THE trimmings or waste from "green" or untanned hides are mechanically cut into shreds and simultaneously tanned by a tanning agent placed in the shredding machine. The resulting fibrous mass is freed from moisture by pressure, and dried. If desired, the sheets of "artificial leather" thus obtained are calendered and again pressed.

—C. A. M.

XV.—MANURES, &c.

Double superphosphates; Analysis of — O. Foerst. Chem.-Zeit., 1909, 33, 685—686.

FOR the extraction of the water-soluble phosphoric acid in double superphosphates, it is not sufficient to shake 20 grms. of the substance with 1 litre of water for 0.5—2 hours as is prescribed for superphosphates. The duration of the extraction for the complete solution of the monocalcium phosphate should be 24 hours, and is not shorter by carrying out part of the extraction in a rotating shaker apparatus. The sample should be ground before extraction and the same results are obtained with 10 grms. as with 20 grms. per litre of water. Of the filtered extract 25 c.c., corresponding with 0.25 gm. of the superphosphate are boiled for 10 minutes with 10 c.c. of fuming nitric acid to destroy the pyrophosphoric acid. An indicator is added and the solution then neutralised as accurately as possible by means of ammonia solution of sp. gr. 0.9. When the liquid is cold, precipitation is effected with ammonium citrate and magnesia mixture in the ordinary way. The moisture in double superphosphates is estimated by drying 5 grms. of the sample in tared watch glass for 6 hours at 100° C.—T. H. P.

Nitrogen-fixing bacteria; Some effects of — on growth of non-leguminous plants. W. B. Bottomly. Roy. Soc. Proc., 1909, B, 81, 287—289.

THE author finds that *Pseudomonas radicola* and *Azobacter* together make a powerful combination for the fixation of free nitrogen. Pot experiments with plants watered with a mixed culture of the two bacteria, compared with plants watered with distilled water, show an increase in weight of 76 per cent. Field experiments on barley showed an increase of 76 per cent. Hyacinths gave an increase of 18.6 per cent., and parsnips an increase of 21.7 per cent. The presence of calcium carbonate in these experiments is necessary.—J. C. C.

Nitrogen; Assimilation of atmospheric — by microorganisms naturally occurring in the soil. F. Strain. Z. Zuckerind. Böhm., 1909, 33, 599—614. (See also this J., 1908, 1167.)

THE author concludes this paper with an account of practical experiments on the inoculation of soil with azotobacter. Direct inoculation of the soil was found to increase the yield of turnips to the extent of 10 per cent. of the roots and 35 per cent. of the leaves, that of oats to the extent of 13 per cent. of the corn and 16 per cent. of the straw, and that of potatoes to the extent of 31 per cent. of the tubers. Further experiments have shown that good results are to be obtained, not by direct inoculation of the soil with pure cultures, but partly by a gradually effected transfer of the culture from a medium of development (mannitol-nutrient solution) to a medium approximating in character to that of natural soil, and then to the soil itself, and partly by inoculation of crude cultures. The method of inoculation is as follows:—Soil, to which 5 per cent. of dextrose has been added, is inoculated with a pure or crude culture of azotobacter (500 c.c. of dextrose-nutrient solution, containing developed azotobacter cultures, were poured into 5 kilos. of soil to which 250 grms. of dextrose had been added); the mixture is kept for 3 months at 24°, whereby the organisms grow and probably become acclimatised to the chemical and biological conditions which obtain in soil under natural conditions. Experiments on a small scale, carried out under glass, and

with potassium chloride, monocalcium phosphate, calcium carbonate, and dextrose, were added to the soil, and that a pot which had not been inoculated with azotobacter, yielded 11.64 grms. of seeds and 19.22 grms. of straw, a pot which had been inoculated with a pure culture of azotobacter yielded 12.64 grms. of seeds and 10 grms. of straw, and a pot, to which had been added 500 grms., inoculated with azotobacter, yielded 29 grms. of seeds and 44.84 grms. of straw.—L. E.

Sugar beets; Sodium chloride (common salt) as a manure — H. Mette. Z. Zuckerind. Böhm., 1909, 3, 620—621.

COMPARATIVE experiments, dealing with the effect of addition of common salt to the soil on the growth of the sugar beet, were made in 1908 (a dry year). The soil, in which barley had previously been grown, was treated with stable manure and mineral fertilisers. On August 1, which date the beets already presented a shrivelled appearance owing to protracted dry weather, salt, in the proportion of 100 kilos. per $\frac{1}{2}$ hectare, was mingled with the soil. It was found that a plot of 100 sq. metres, treated with salt, yielded a crop of 295.4 kilos, as compared with a crop of 272.3 kilos, from a plot of the same size which had not been treated with salt, and, in the former case, the sugar-content of the roots was 21.48 per cent., as compared with 20.58 per cent. in the latter. The author considers that this striking result is to be traced, not to the direct manurial action of the sodium chloride, but to its hygroscopic power. The salt takes up, and retains moisture; the nutrient material is thus kept in the liquid state, and further development of the beet is insured. The author concludes that manuring with salt is practically valueless in the case of good soils in a temperate climate and with normal rainfall, but that excellent results can be obtained by such treatment (even though the salt is applied at a very late period, as in the case quoted above) in the case of light soils in a hot climate with a long period of dry weather.—L. E.

Fertilisers Act, 1909; Canadian — Board of Trade J., July 1, 1909. [T.R.]

The "Fertilisers Act, 1909" (No. 16 of 1909) which was enacted on May 19th last, repeals the Fertilisers Act of 1906 with effect from January 1st, 1910, and provides that every brand of fertiliser offered for sale in Canada shall bear a permanent registration number, which will be allotted by the Minister of Inland Revenue on application of the manufacturer of such brand of fertiliser, or his agent, on payment of a fee of two dollars. Every application for a registration number, which is to be affixed in plain and legible manner to every package of fertiliser offered for sale, must be accompanied by a statement giving—(a) Name of brand for which registration number is asked, and trade mark, if any. (b) Name and address of manufacturer. (c) Name and address of the person applying for registration. (d) Guaranteed analysis. Materials from which the fertiliser is made.

A licence—costing 5 dols.—is required for the sale of a fertiliser, and such licence shall be valid for the calendar year in which it is issued. The purchaser of any registered fertiliser may, under certain conditions, obtain an analysis thereof on payment of a fee of one dollar. The Act is not applicable to any fertiliser imported for the personal use of the importer and not for sale, nor to fertilisers which are manufactured to the order of the purchaser and are not intended for sale; but an analysis of such fertilisers may be obtained, under certain prescribed conditions, on payment of a fee of 5 dollars.

As provided in the Act that "fertiliser" shall mean any natural or artificial manure containing phosphoric acid or nitrogen or potash, except ordinary stable manure.

XVI.—SUGAR, STARCH, GUM, &c.

Asian corn [maize]; Use of — for the manufacture of starch, glucose, etc. L. E. von Cramm. Seventh Int. Congr. Appl. Chem., London, 1909.

Maize is cultivated in large districts in South Russia, as Bessarabia, Odessa, and that part of the Caucasus

controlled by the Vladikawkas Railway from Rostoff to Vladikawkas towards Batoum and Novorossisk. At present, nearly the whole of the maize is used for home consumption and is of poor quality, but if a better outlet could be obtained, the quality might be improved and cultivation extended. The price for maize f.o.b. Novorossisk is, on the average, £3 5s. per ton. It is suggested that in the districts of the Caucasus and in the valleys of Bessarabia which are too distant for remunerative export of the maize, the latter should be employed for the manufacture of starch, dextrin, glucose, etc., for export.—A. S.

Sugar cane in the Leeward Islands; Manurial experiments on — Dept. of Agric. for the West Indies, 1909. [T.R.]

NITROGENOUS fertilisers, such as ammonium sulphate and sodium nitrate, are necessary and remunerative for ratoon canes, while phosphates and potash do not appear to be advantageous.

Indanthrene Blue and Indanthrene Violet as substitutes for ultramarine in sugar works. Internat. Sugar J., 1909, 11, 320.

THE above dyestuffs possess advantages not present in the ultramarine at present used. Under the action of acids and bases there is no change in colour or intensity. This stability in colour is an important essential in beet sugar manufacture, for the juice always contains free bases. The dyestuffs are introduced into the pan in quantities depending upon the kind of sugar in view. Sugar from the centrifugals is of a superior whiteness, with a slightly blue hue very pleasing to the eye. In the refineries it is found that 45 grms. of Indanthrene make an excellent substitute for 75 grms. of ultramarine blue.

Molasses; Determination of sucrose in — A. C. Andersen. Compt. rend. Trav. lab. de Carlsberg, 1909, 7, 243—246.

THE author finds that mercuric nitrate is an excellent defecating agent for coloured sugar solutions. The reagent is prepared as follows:—220 grms. of red mercuric oxide are added carefully, and with thorough shaking, to 160 c.c. of nitric acid (sp. gr. 1.39); the whole is then shaken for some minutes, treated with 160 c.c. of water, and slowly heated to boiling. When solution is complete, the whole is cooled to the ordinary temperature, treated with 60 c.c. of 5 per cent. solution of sodium hydroxide in order to neutralise the bulk of the excess of nitric acid, made up to 1 litre, filtered, and preserved in a dark glass bottle. The author has determined the sucrose-content (by direct polarisation) of a sample of molasses, using solutions of various concentrations clarified with various quantities of the mercury solution. The procedure consisted in adding the mercury solution to 25 c.c. of the molasses solution, immediately neutralising with sodium hydroxide solution (the solution being kept cooled during neutralisation), making up to volume (100 c.c. plus 0.2 c.c. for each 10 c.c. of mercury solution), mixing, filtering, and polarising the filtrate. It was found that with increasing quantities of the mercury solution, the polarisation reading increased at first, and then remained constant. Experiments with pure sugar showed that with the above-described procedure, accurate results are obtained. The removal of colouring matters and of leucostatory substances (proteins, etc.) present in the molasses, requires a certain quantity of mercuric nitrate, but an excess of this reagent does not affect the determination of the sucrose by polarisation.—L. E.

Honey; Artificial — A. Jägerschmid. Z. Unters. Nahr.-und Genussm., 1909, 17, 671—672.

ARTIFICIAL honey prepared from invert sugars show reactions due to the presence of furfural, methyl furfural, and hydroxymethylfurfural derived from the caramelisation of the sucrose during inversion. These furfural derivatives are volatile with steam and may be detected in the distillate by means of aniline acetate reagent. The distillate from genuine honey gives no red coloration with aniline acetate, but that from commercial invert syrup, even when mixed with 75 per cent. of genuine honey, gives a

marked coloration. The distillates from genuine honey possess a pleasant aroma which is absent from those of artificial honey. The coloration obtained on the addition of aniline acetate to the distillate from artificial honey sometimes requires a minute to develop; it frequently fades away in about 15 minutes, but re-appears more faintly on the addition of acetic acid. When examined spectroscopically, the red is seen to be more carmine in colour; there is next a yellow band and then a dark olive-green line; the blue disappears almost entirely and becomes bluish-black. If honeys containing invert sugar be extracted with acetone, and hydrochloric acid be added to the acetone extract, a red coloration is developed. In the spectroscope a broad black band follows the red, and the green and blue remain; on dilution with acetic acid, the broad black band becomes olive-green. The acetone extracts of pure honey, when treated with hydrochloric acid, do not change the spectrum except after long standing. The acetone used must be quite pure; when treated with hydrochloric acid it should develop only a slight yellow coloration.—J. F. B.

Fucose. B. Tollens and F. Rorive. Ber., 1909, 42, 2009—2012.

50 GRAMS of fucose were obtained from 6000 grms. of *Fucus* from Heligoland. Fucose does not form a crystalline hydrate; it exhibits mutarotation. When the solution is examined 10 minutes after preparation, the rotatory power is $[\alpha]_D = -124$, falling to $[\alpha]_D = -75.6^\circ$ in the course of $1\frac{1}{2}$ —2 hours; the calculated initial rotation is $[\alpha]_D = -150$. The constant rotation of the fucosehexonic acid prepared by the addition of hydrogen cyanide is $[\alpha]_D = +37.6$. The trihydroxyglutaric acid obtained by oxidation with nitric acid has $[\alpha]_D = +27.6^\circ$; two preparations of the potassium salt showed $[\alpha]_D = -8.2^\circ$ and -8.7 , whereas the corresponding acid from rhamnose has $[\alpha]_D = -24.9^\circ$ and its potassium salt $[\alpha]_D = +8.5$. The two acids are thus optical antipodes, and accordingly fucose has the configuration:

—E. F. A.

Starch granules; Microscopical study of changes occurring in — during germination of wheat. Effect of mineral acids, enzymes, and heat on granules of various starches. R. Whymper. Seventh Int. Congr. Appl. Chem., London, 1909.

SECTIONS of wheat grains cut longitudinally through the embryo or germ and transversely through the middle of the grain were studied microscopically over a period of growth of 14 days. When the grain had become thoroughly moist from standing on wet flannel for 36 hours, the larger starch granules nearest the germ began to show signs of surface pitting. After 3 days the grain had increased in size by about one-eighth, and the starch granules near the germ and in the centre of the flanks were considerably swollen, and in many cases pitted owing to enzyme action. Long oval starch granules, which showed no visible signs of attack, also began to make their appearance, and on the ninth day the majority of the starch granules were of the oval form. After this time the path of decomposition could be traced upwards and towards the centres of the flanks of the grain, the germ growing rapidly at the expense of the starch and protein matter, which, as they were removed, left a cavity up the outer side of the grain. The larger and more mature starch granules were the most readily assimilated as plant food; no markings could be observed on the smaller granules, even with the highest magnification, up to the sixth day.

There appears to be no general relation between the size of starch granules and the ease with which they are attacked by diastase, mineral acids, and wet and dry heat, although almost invariably the larger granules of any one starch succumb more quickly to attack than smaller granules of the same kind. The temperatures of gelatinisation of a large number of samples of barley, maize, rye, potato, rice, wheat, and tapioca starches were determined by exposing the starches to a gradually rising temperature and examining them microscopically. The

values obtained differed in some cases from those recorded previously, and also varied with the state of maturity of the starch granules.—A. S.

Starch; Determination of —. M. Buisson. Seventh Int. Congr. Appl. Chem., London, 1909.

BAUDRY'S method for the determination of starch (Bu Assoc. Chim., 1892, 9, 354), in which the starch is rendered soluble by heating with salicylic acid, presents certain disadvantages when applied to potatoes and flour. The author has obtained better results by using picric acid instead of salicylic acid. The normal weight (for 1) polarimeter employed) of the finely divided potato pulp is treated with 100 c.c. of water and 25 c.c. of an aqueous solution of picric acid saturated in the cold, and heated for 45 mins. at about 115°C . in a calcium chloride bath. 80 c.c. of cold water are then added, the whole cooled to 15°C ., made up to 200 c.c., and filtered through dry filter. The filtrate is then examined in the polarimeter in a 400 mm. tube. For commercial starches, 15 c.c. picric acid and 100 c.c. of water are used, and the duration of the boiling is 30 minutes; whilst for wheat flour 50 c.c. of picric acid are used, the other conditions being the same as for potato pulp. If the solution after filtering is opalescent, it is mixed with about 1 gm. of kieselsol and again filtered.—A. S.

Molecular and solution volumes of colloidal carbohydrates [starch and cellulose]. C. F. Cross and E. J. Beyer. Ber., 1909, 42, 2198—2204.

THE authors, in a preliminary note, draw attention to the application to such substances as starch and cellulose of the methods developed by Traube (Ber., 1895, 28, 41; Annalen, 1896, 290, 43), based on relations between the molecular and molecular solution volumes of compound and their molecular weights and constitutions. Tentative attempts in this direction have shown that the molecular and molecular solution volumes of starch and cellulose as calculated from available experimental data are much lower than the values calculated by Traube's method and it is suggested that this may possibly be due to the formation in the molecules of the substances mentioned.—A. S.

Sodium chloride as manure for sugar beets. Mett See XV.

PATENTS.

Beet juice; Defecation of crude — by the use of centrifugal separators. Aktiebolaget Separator. Fr. Pat. 397,383, Dec. 14, 1908.

THE crude juice, previously heated to about 85°C ., continuously mixed with the fluid saturation-mud separated in the centrifugals which clarify the juice after carbonatation and saturation. Together with this mud a small proportion of dry lime, amounting to 0.05—0.1 per cent., is added to the juice. In certain cases sodium carbonate may be used instead of lime. The juice clarified by decantation and the residual mud is separated in continuous centrifugal separators. The clear juice is then defecated with lime in the usual manner and saturated with carbon dioxide; the precipitate is separated in centrifugal separators and the saturation-mud so obtained is used for defecating a further quantity of crude juice.—J. F. B.

Sugar cane; Preliminary treatment of — for extraction of the juice. C. Steffen. Fr. Pat. 397,672, Dec. 1, 1908.

In order to open up the cells of the sugar cane which contain the juice and to destroy the coherence of the fibres, the sugar cane is cut or chopped into pieces from 60 to 150 mm. in length. These pieces are then beaten to a fibrous mass in a centrifugal mill or disintegrating machine and the juice thus liberated is extracted either by pressure or diffusion.—J. F. B.

Masseuite; Process for the dilution, heating, and refining of — W. Schäfer. Ger. Pat. 209,565, Sept. 26, 1908.

STEAM at a suitable pressure is introduced into the space above the surface of the masseuite contained in closed covered heaters. The steam gives up its heat not only to the surface of the masseuite, whence it is transmitted through the whole mass owing to the action of the stirrer mounted in the heater, but also to the walls of the heater. The condensed water deposits in minute drops, so that there is a gradual continuous dilution of the adherent juice without any solution of the crystals, and also there is no introduction of non-sugar materials.—A. S.

Sugar juice and other solutions; Apparatus for the evaporation of — W. Greiner. Ger. Pat. 210,337, April 29, 1908.

THE patent relates to a process in which the sugar juice passes in succession through a number of connected evaporators. The first evaporator is heated by exhaust steam, and the vapour generated therein is passed not to the next, but to a more distant evaporator and thence in succession through the following ones, whilst the second evaporator is heated by fresh steam, and the vapour generated therein passed to the following evaporators in the usual manner. It is stated that in this way a better utilisation of the steam heat is attained.—A. S.

Boiling of sugar juices and syrups; Apparatus for controlling the — F. Langen. Ger. Pat. 210,543, Oct. 22, 1908.

IN the boiling of sugar juices and syrups it is important that the water-content be kept at a definite figure during definite periods of the process. The water-content is not easily determined by measuring the difference between the b. pt. of the juice and the b. pt. of water at the same pressure. The apparatus described in the patent is claimed to possess advantages over the so-called "osmoscope" usually employed for this purpose. It consists of two or more thermo-elements, with one junction in the boiling juice or syrup and the other in saturated steam at the pressure under which the liquid is boiling, are combined with a galvanometer, which indicates the difference in temperature, or, by means of a suitable scale, the corresponding water-content of the boiling liquid. In order to avoid possible overheating of the junction of the thermo-element exposed to the steam, it is disposed in a closed chamber connected to the vapour-space of the juice-boiler, and steam is continuously led into this chamber, means being provided whereby before the steam enters the chamber, so much heat is withdrawn from it, that its total heat is the same as that of saturated steam at the pressure prevailing in the vapour-space of the juice-boiler.—A. S.

VII.—BREWING, WINES, SPIRITS, &c.

Dead cells of yeast; Criticism of staining methods for determining the — E. Schlichting and H. Winther. Tenth Int. Congr. Appl. Chem., London, 1909.

ACCORDING to the authors the methods most generally followed in commercial laboratories for the determination of dead cells in samples of yeast are not sufficiently accurate for technical purposes. Definite conditions should be strictly adhered to, different concentrations of "stain" being liable to lead to erroneous results. The staining medium found most satisfactory was a solution of "sulpho-indigotate" at a dilution of 1:30, whilst the most appropriate dilution for the yeast was about 40 cells per cb. mm.—A. S.

PATENTS.

Malt for brewing; Mashing — B. W. Valentin, Llandely, Wales. Eng. Pat. 6087, Mar. 13, 1909.

IN the case of malts which in the ordinary way of mashing yield worts deficient in yeast foods, the proportion of the latter may be increased by mashing a fraction of the grist (10–15 per cent.) separately at a temperature which is below that which is unfavourable to the extraction of yeast foods. The most suitable temperature for this mash is 120° F., the goods being "stood" at this temperature for one or more hours, and then discharged through a mashing machine, together with the main bulk of the grist, to make up a mash at an initial temperature of 150°–155° F.—J. F. B.

Brewing; Art of — M. Henius, Chicago. U.S. Pat. 925,700, June 22, 1909.

MALT and a cereal product, such as prepared corn (maize), rice, or the like, are mashed separately, and a portion of the malt wort is then introduced into the cereal mash in order to partially invert the starch in the latter. The mixture is next boiled, and a further quantity of malt wort is added in order to complete the inversion. Finally, the whole mixture is boiled.—W. P. S.

Spirits; Process and apparatus for distillation and treatment of — J. E. Carroll. First Addition, dated Dec. 9, 1908, to Fr. Pat. 376,151, March 26, 1907 (this J., 1907, 985). Under Int. Conv., Aug. 12, 1908.

THE apparatus as now modified comprises a superheating arrangement, having its branch pipes connected with the pipe leading from the still to the condenser at points above the central axis of the latter pipe, so that none of the condensed liquid can pass into the superheater. The steam-jacketed apparatus composing the superheater is composed of several members, each containing a large number of small tubes surrounded by a closed steam jacket, the connection between the adjacent series of these tubes being effected by a union head at each extremity, so that the direct passage of the vapour from one end of the superheater to the other is impeded. The air which is delivered to the superheater undergoes a preliminary heating by means of a steam-jacketed coil before being injected into the vapour pipes of the superheater.—J. F. B.

Lactic acid bacteria; Process for the preparation of pure or mixed cultures of — in a dry condition. Löföf and Mayer. Ger. Pat. 210,988, Oct. 30, 1907.

THE product obtained by growing lactic acid bacteria (pure or mixed cultures) in skimmed milk is filtered or centrifuged, and the mixture of casein and bacteria thus obtained is washed with sterilised water to remove the milk serum, then compressed, and mixed with lactose, proteins, or other suitable substances so as to yield a dry powder.—A. S.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A).—FOODS.

Cutin of woody fibre [of cereals]; Nature of the — W. Sutthoff. Z. Unters. Nahr. und Genussm., 1909, 17, 662–663.

THE residue from the treatment of the woody fibre of cereals by hydrogen peroxide in ammoniacal solution, according to König's indications (this J., 1906, 1069), consists of cellulose and cutin. The latter may be separated from the cellulose by treatment with cuprammonium solution, in which it is insoluble. In this way the cutin of rye-bran was isolated, containing 15–34 per cent. of ash, consisting of almost pure silica. Combustions of this impure product, corrected for the ash, indicated 69–70 per cent. of carbon and 11–12 per cent. of hydrogen for the cutin. On boiling for 3 hours with a 20 per cent. solution of potassium hydroxide, the cutin is decomposed.

From the solution the author has extracted by means of light petroleum spirit, a small quantity of a greyish-white crystalline wax-alcohol, melting at 55°–56° C., and having a composition approximating to that of cetyl alcohol or octadecyl alcohol. On acidifying the residual liquid a flocculent precipitate was obtained, soluble in light petroleum spirit, and solidifying on freezing to a mass melting indefinitely at about 30° C., and corresponding in composition to nonyl or capric acid. This product, however, is doubtless a mixture of acids.—J. E. B.

Wheat; Influence of environment on the composition of —.
J. A. Le Clerc and S. Leavitt. Seventh Int. Congr. Appl. Chem., London, 1909.

Two samples of wheat, a spring variety and an autumn variety, were grown at three localities in the United States, differing widely in climatic conditions. The former, a durum wheat (Kubanka), was grown in S. Dakota, Kansas, and California; and the latter, a common wheat (Crimean), was grown in Texas, Kansas, and California. At each place three plots were employed for each of the two kinds; on one plot the home-grown seed was sown, and on the others, seed from the other two localities. It was found that all three plots in one locality gave seed identical in composition and in appearance, whilst the same seed grown at three different places varied to a very great extent. For example the Crimean wheat grown in Kansas, in California, and in Texas during 1907, gave the following results:—

	Kansas.	California.	Texas.
Protein, per cent.	22.3	11.0	17.6
Weight per 1000 corns ..	21.0	33.4	23.0
Weight per bushel	51.0	61.7	58.0

On the other hand, when seeds varying in chemical and physical characters, as shown by the results in the table, were grown side by side in Kansas, the three plots gave crops identical in composition and in appearance. They also yielded in Texas crops which were identical from the three plots, but which were quite different from those obtained in Kansas. The results show that climatic conditions have a much greater influence than the seed and soil on the character of the crop. If it be desired to improve a certain crop, the best method is by selection or otherwise in the locality in which it is to be grown, rather than by growing seed which has been bred in another locality. (See also this J., 1909, 336.)—A. S.

Flour; Changes suffered by — on keeping. F. Marion.
Seventh Int. Congr. Appl. Chem., London, 1909.

FIVE "Corbeil" flours of good quality, manufactured during March to May, were kept at the ordinary temperature for 2 years in small sacks; and each month, determinations of moisture, gluten, gliadin, fatty matter, and acidity were made, the results being referred to the dry substance of the flour. The amount of fatty matter diminished on keeping, and in some cases the flours acquired a rancid flavour. From the results for dry gluten, gliadin, and acidity, curves were plotted. The content of gluten was nearly constant during the first 5 months and showed only slight variations up to the nineteenth month, after which, however, it was found very difficult to wash the dough in a stream of water, and the decomposition of the gluten was very marked. The gliadin curve showed a maximum at 3 months, a minimum at 7 months, a second maximum at 15 months, and another minimum at 18 months. These results are in agreement with the practical observation that flour which has been kept for 3 months still retains its bread-making qualities, but is no longer suitable for the bakery after keeping for 6–7 months. The acidity increased during the first year, and then fell slowly and regularly, probably owing to ammonia, etc., being produced by the decomposition of the gluten.—A. S.

Wheat and flour; Mineral composition of —. L. J. Vuadart. Seventh Int. Congr. Appl. Chem., London, 1909.

The author determined the nitrogen, phosphoric acid and potash in different specimens of wheat, the result being shown in the following table. The first three samples were commercial seed wheats. The nine following were grown as spring wheats on the same field, Nos. 1 being supplied only with nitrogenous manure, Nos. I. with nitrogen and phosphoric acid, and Nos. III. with nitrogen, phosphoric acid, and potash. The heavy and light varieties of "Bon fermier" wheat were obtained by selection by means of sugar syrup. The last two specimens were Upper Egyptian wheats consisting of white wheat with elongated corns mixed with a little hard wheat.

It will be seen that the ratio of phosphoric acid to nitrogen, and, in a lesser degree, that of potash to nitrogen, is fairly constant. Analogous results were obtained with the flours prepared from the wheats (yield of flour, 70 p. cent.), as shown in the following table. In both cases (wheats and flours) the results are calculated with respect to material containing 15 per cent. of moisture.

Description of samples.	Nitrogen.	Phosphoric acid.	Potash.	Phosphoric acid per 100 of nitrogen.	Potash per 100 of nitrogen.

The author also investigated the distribution of phosphoric acid in the flour (Saumur I. of the above table). It was found that of the total phosphoric acid, 66 per cent. was contained in the starch, 13.8 per cent. in the purified gluten, 2.4 per cent. in the ether-alcohol extract of the gluten, and 17.8 per cent. in the wash-waters.—A. S.

Wheat; Laboratory experiments on the determination of the milling and bread-making qualities of —.
Holdeffless and R. Wessling. Seventh Int. Congr. Appl. Chem., London, 1909.

TWO authors have made a series of experiments with the object of devising exact laboratory methods for ascertaining the milling and bread-making qualities of wheat. The results obtained were briefly as follows:—(1). With an experimental (Seck) mill it was found possible with 10 lb., or even with 5 or 4 lb. of wheat, to obtain a normal grinding, the results as to yield of flour being comparable with those obtained on the large scale. (2). With the mill, the variation of the grinding conditions according to the nature of the wheat could be studied, and also the effect of moistening the grain. (3). In baking tests

experimental oven, normal loaves were obtained both with 50 grms. and with 400 grms. of flour. (4). The quality of the bread could be judged most satisfactorily when the loaves were baked not, as usual, in moulds or shaped supports, but on large firebrick slabs. (5). The best material for raising the dough was found to be pressed yeast. In order that comparisons could be more easily made, a large proportion of yeast (2 grms. to 50 grms. of flour) was used; this had no injurious effect on the taste or quality of the bread. (6). Distinctions between different kinds of wheat could be more readily observed in milk loaves than in ordinary loaves; in the preparation the former, some sugar is added and hence the activity of the yeast is increased. (7). The loaves were compared with respect to volume (best determined by Reisch's method), appearance, shape, colour, and condition of the interior (crumb). The results obtained with a number of different wheats by the laboratory methods described are given in the following table:—

	Protein content of wheat dry substance, per cent.	Mealy corns, per cent.	Steady corns, per cent.	Weight of 100 corns in grms.	Yield of flour, per cent.		Bran, per cent.	Protein content of flour per cent.		Volume of loaves per 100 grms. of flour, in c.c.				Water-absorbing power of 10 grms. of flour.

NOTE.—With mixtures of flours the size of the loaf was the arithmetical mean of the sizes obtained with the component flours separately. For improving the appearance and taste of the bread, it was found most advantageous to use blends of more than two kinds of flour.

—A. S.

flour; Analysis of — with respect to its bread-making value. T. Kosutány. Seventh Int. Congr. Appl. Chem., London, 1909.

THE weight of the loaf which can be prepared from a given quantity of flour depends in the first place upon the quantity of water the flour is capable of absorbing in the preparation of the dough; this again depends upon the water content of the flour, which may vary from 9 to 16 per cent., so that the water-absorbing powers of two flours of exactly similar composition may show differences of as much as 7 per cent. Hence in buying flour the water-content should not be regarded. Besides moisture, the content of starch and of gluten must be taken into consideration. Starch is only capable of taking up 50–60 per cent. of water, and hence cannot be wholly responsible for the water-absorbing power of the flour, which is capable of absorbing up to 90 per cent. and still yield a dough of proper consistency. The controlling factor with respect to water absorption is the gluten, which can take up 300–350 per cent. of water. The character of the gluten is of importance in this respect, gliadin having a greater water-absorbing power than glutenin. If the flour be deficient in sugar or in enzymes capable of producing sugar during kneading, salt preparations or sugar should be added, in order that sufficient carbon dioxide be produced during the fermentation to produce loaves of the requisite size. The retention of the carbon dioxide is dependent upon the character of the gluten, the gliadin being the important constituent in this respect also. In order that the gas bubbles be small and of uniform size, it is essential that the yeast be evenly distributed throughout the dough and that yeast cells of approximately the same age and belonging to the same race be employed. From the above

considerations it will be seen that the quantity and character of the gluten are the most important factors governing the quality of a flour. The gluten is determined most readily by washing the dough. The gliadin is best determined by evaporating an extract of the flour prepared with 70 per cent. alcohol. The water-absorbing power may be ascertained by placing on the dough a ball of 3.5 cm. diam. loaded with shot so that it weighs 100 grms. In dough of the proper consistency this produces a depression of 30–32 mm. diam. in 12–15 secs. The consistency of the dough can be determined more accurately by means of the perforation apparatus of Rejtő.—A. S.

Mechanical kneaders [bread-making]; General results furnished by —. Arpin, Ringelmann, and Lindet. Seventh Int. Congr. Appl. Chem., London, 1909.

TESTS carried out with a number of mechanical kneading machines recently in Paris led to the following results. The different machines did not furnish doughs of the same

quality, but during the fermentation the gluten became hydrated, and the finished loaves were almost identical with respect to quality and yield. The loaves were of the same quality and size as those made by hand with similar amounts of flour, water, salt, and yeast, and baked in the same oven. The power required in the kneading rapidly rose to a maximum and then remained constant up to the end of the operation. The total mechanical work varied within wide limits with different machines, viz., during the 6–13 minutes occupied in the kneading and after deducting that performed by the machine *in vacuo*, "from 16–664 to 175–983 kilogram-metres" for 172 kilos. of dough, the maximum power varying from 0.41 to 5 h.p. per second. A workman kneading by hand furnished during the 30–35 mins. of the operation a force of 9.5–11.9 kilogram-metres per second.—A. S.

Parity fermentation; Researches on —. A. J. J. Vandevelde. Bull. Soc. Chim. Belg., 1909, 23, 267–283.

BESIDES the gluten, insoluble in water, cereal flours contain soluble proteins which are removed in the course of kneading, when this operation is adopted for the isolation of the insoluble proteins. This is why the proteins recovered by kneading do not correspond with the quantity calculated from the nitrogen of the flour. When the gliadin has previously been extracted by alcohol, the gluten cannot be separated in the usual manner. Gliadin, isolated and mixed with starch, will not form a dough, but when isolated gliadin is mixed with whole flour, it may be recovered quantitatively by kneading, together with the gluten of the flour. The author has made experiments in order to ascertain whether the gluten plays a definite part in parity fermentation, or whether

its action is merely the mechanical occlusion of the gases. For the determination of the results of panary fermentation, the author has modified Boutroux's method for measuring the rising of the dough. He employs cylindrical glass tubes of 2.7 cm. internal diameter and 25 cm. in length. Forty grms. of dough containing yeast are introduced into the tube, and the end at which it has been charged is closed with a cork. The dough is pressed down by means of a wooden piston from the other end, in order to expel all the air and make a solid mass against the cork. The tubes are then placed in a vertical position at a temperature of 20° C., and the increase in height of the dough is noted after 4 hours and after 24 hours. Further observations on panification have been made by determining the density of the loaves, by measuring their volume by the displacement of fine sand in which they are immersed in a suitable vessel. The fermentation experiments showed that the fermentative energy (expansion of the dough in a given time) is inversely proportional to the gluten-content of the flour. On the other hand the panification tests showed that the density of the loaves decreased as the proportion of gluten in the flour increased. Hence it is concluded that the action of the gluten is essentially mechanical. The elastic properties of the gluten cause the compression and retention of the gases in the dough during fermentation and permit of their expansion during baking, thereby increasing the volume of the loaves. When flour is heated, either dry or in presence of moisture, the elastic properties of the gluten are destroyed. After heating for 10 hours at 100° C., 6 hours at 120° C., 2 hours at 150° C. or 30 minutes at 175° C., the gluten of the flour is no longer elastic, and the proteins cannot be separated from the starch by the operation of kneading. The same action takes place still more rapidly if the flour is heated in a moist atmosphere, 30 minutes at 100° C. being sufficient to make it impossible to separate the gluten by kneading; a larger quantity of water is required to make a dough than with normal flour, and the dough disintegrates entirely when kneaded. It was thus possible, by various conditions of heating, to make a flour which contained any proportion of elastic gluten which might be desired. Fermentation experiments, made with a flour thus modified in different degrees, showed that the rising of the dough was greater, the lower the degree of modification produced. Moreover, panification tests confirmed this, and the modification of the gluten by heat gave loaves of correspondingly greater density. In order to ascertain whether the gluten undergoes any chemical change in the course of panary fermentation, the author prepared dough containing yeast and determined by the kneading process the yield of elastic gluten recoverable after 24 hours: the quantity recovered was only slightly lower than that yielded by the original flour. Thus gluten is the essential factor of the absorption of water in doughing and a mechanical agent, which although playing no appreciable part in the fermentation, is really the agent of panification, without which the production of loaves would be impossible.—J. (B).—SANITATION; WATER PURIFICATION.

Cholera vibrio; Vitality of the — in artificially infected samples of raw Thames, Lee and New River water with special reference to the question of storage. A. Houston. Metr. Water Board. Fourth Report of Research Work, 1909.

It was found that cholera vibrios died very rapidly in raw river water after artificial infection, as the result of storage in the laboratory. At least 99.9 per cent perished in 1 week and all of them within 3 weeks. The isolation of the cholera vibrios in the raw river water after artificial infection, presented no difficulty even when the numbers added were very small; while microbially to be mistaken for true cholera vibrios were not found in any duplicate, but non-infected, samples of the same waters. The advantages of storing river water from the point of view of typhoid fever have been previously shown (see this J., 1908, 873), and the same conclusions apply to cholera; the time, also, required to ensure safety in the former case being more than sufficient in the latter. These conclusions emphasise the point that by adequately storing the raw river water prior to filtration, the safety of the metropolis as regards epidemic of water-borne disease is substantially assured.—J. H. J.

Oxides of nitrogen and their compounds with metals (iron and lead); Formation of — in the production of ozone for sterilising water. E. Bonjean. Compt. rend. 1909, 148, 1765—1766.

APPRECIABLE quantities of oxides of nitrogen are formed during the process of ozonising air for the sterilisation of water, and these, attacking any metals with which they may come in contact, such as iron or lead pipes, cause their rapid corrosion, leading even to the complete obstruction of the plant and serious contamination of the water to be treated. All metals, and particularly lead, should therefore be proscribed in the construction of parts of the apparatus which may be exposed to the ozonised air.—F. SOMM.

Nightsoil; Apparatus for reducing — and recovering ammonia therefrom. K. E. Fryklind, Stockholm Sweden. U.S. Pat. 918,741, April 20, 1909.

THE apparatus is continuous and uniform in working and produces a dry nightsoil lime practically free from smell, and containing any desired percentage of lime. A large amount of ammonia is, at the same time, recovered. The nightsoil is subjected to a preliminary agitation by means (1), of a rotating stirrer, and (2), of a grating swinging up and down. It then passes to a closed holder which is always filled at a constant pressure. This closed holder is connected to a cylindrical vessel, which is, at the front end, provided with a feeding apparatus for quicklime, and has a rotating stirrer which mixes the nightsoil and lime and feeds the mixture towards the back end of the cylinder. The lime is slaked during its passage through the cylinder, and the larger part of the nitrogen present is driven off as ammonia and recovered by absorbing in sulphuric acid.—G. W. McD.

Garbage and rendering apparatus; also, process of extracting grease and oil from garbage. C. S. Wheelwright, Bristol, R.I. U.S. Pats. 925,970 and 925,971, June 22, 1909.

THE apparatus consists of a digester connected at its lower end with a chamber adapted to the further treat-

ent of material after it has been cooked in the digester. The ram, actuated from the outside, is provided in the digester for the purpose of forcing the material through the passage-way between the digester and the receiving chamber; the movement of the ram opens and shuts a live in the passage-way. The garbage is saturated with hot water, drained, and forced into the digester where it is heated with steam under pressure; water is added during the heating process, and the cooked material, together with the water and oil are then withdrawn from the vessel, the oil being separated subsequently from the water. These operations are carried out in a continuous manner. The water separated from the cooked material and oil is used for saturating and cooking a fresh supply of garbage.—W. P. S.

Wage treatment apparatus. K. Imhoff, Bresdeny, Germany. U.S. Pat. 924,664, June 15, 1909.

XIX.—PAPER, PASTEBOARD, &c.

Paper pulp; Measuring absorption of dyestuffs by —. H. Wrede. Papier-fabrikant, 1909, 7 (Fest-und Auslandsheft), 43—46.

In the dyeing of paper pulp it is generally desirable to take the dyestuff by precipitation, in which case a colourless "backwater" is obtained, and the only loss of colouring matter is that which arises from the passage of particles of the precipitate through the felted mass of fibres on the wire. The economy of this method of operation depends very largely on the degree of mechanical separation of the pulp; a finely milled pulp "carries" the coloured precipitate more readily than a "free", beaten pulp. In certain cases, particularly with unsized papers, the dyestuff cannot be precipitated and the paper-maker has then to rely on specific affinity or absorption of dyestuff by the fibre. This specific affinity varies according to the chemical nature of the dyestuff and the chemical character of the fibre. Pulps which are only lightly boiled and bleached retain residual traces of incrusting matters which have a special affinity for basic dyestuffs, whilst fully purified cellulose pulps show a particularly strong affinity for substantive dyestuffs. A determination of this specific affinity between fibres and dyestuffs is therefore a valuable means for investigating the nature of either of the reacting substances. The author describes an empirical method for measuring this property:—25 grms. of dry pulp are moistened with water and beaten up to a uniform mass with a wooden stick. The fluid pulp is transferred to a litre measuring flask, 200 c.c. of a 1 per cent. solution of the dyestuff are added and the volume is made up to 1 litre. After standing for one hour, with occasional agitation, the coloured liquid is filtered off on a wire sieve and the pulp is pressed and dried for future reference. An aliquot portion of the clear filtrate is placed in a 1 litre cylinder, and its colour is matched exactly by adding a 1 per cent. solution of dyestuff from a burette to a litre of water in another cylinder. Thus the weight of dyestuff absorbed by the fibre may be calculated. As a type of basic dyestuffs, "methylene blue" may be used, and as a type of substantive dyestuffs, "dianil blue." The quantity of dyestuff absorbed increases with the time up to 5 hours; it increases with the temperature up to a certain point, but decreases again at high temperatures; it also increases with the concentration of the solution.—J. F. B.

"Kraft" (Strong) papers; German —. A. Klein. Papier-fabrikant, 1909, 7 (Fest-und Auslandsheft), 24—25.

The very strong, thin wrapping papers first made in Sweden under the name of "Kraft" papers, are now also largely manufactured in Germany. These papers are prepared from spruce or pine woods by the alkaline process of digestion. Generally speaking, young trees, felled in the winter give the strongest papers, but in selecting the wood, account must be taken of local conditions. Spruce wood, especially that grown at high altitudes, gives a more pliable, softer fibre than pine wood,

but many of the German "Kraft" papers are prepared from the latter. The digestion may be effected either with direct or indirect steam, generally in large vertical digesters. The digestion lye varies in density from 8° to 15° B. The weaker lye gives a higher yield, but requires a longer digestion than the more concentrated. The composition of the lye varies according to whether the whole of the alkali lost is replaced by sodium sulphate or whether a mixture of sulphate and carbonate is used. In the former case, the lye contains 20—25 per cent. of its alkali in the form of sulphide, the rest consisting of caustic soda and other sulphur compounds. In the mixed process, the alkali contains only 6—10 per cent. of sulphide and more caustic soda; frequently also the proportion of sulphite is higher. An important feature of the manufacture of kraft papers is the use, together with the fresh "white" lye, of 50—75 per cent. of a once used "brown" lye, which imparts the rich brown colour characteristic of these papers. The temperature of the digestion depends on the time allowed, the pressure employed ranging from 7 to 10 atmospheres and the time from 1 to 3 hours. The best results are obtained with pressures of 6—8 atmospheres, weak lyes and a digestion period of 1½ hours. In reducing the boiled mass to pulp the kollergang plays a very important part, since it is necessary that the fibres should be well milled without reducing their length. The mechanical preparation and the working on the paper machine require careful attention in order to develop the maximum strength, toughness and elasticity. The economy of the manufacture depends very closely on the efficiency of the means adopted for the recovery of the soda used for the digestion, the proportion recovered in a well appointed mill being 85—90 per cent.—J. F. B.

Molecular and solution volumes of colloidal carbohydrates [starch and cellulose]. Cross and Bevan. See XVI.

German paper industry in 1908. Board of Trade J., July 8, 1909. [T.R.]

WHEREAS in 1907 orders were plentiful and the paper factories in Germany were well occupied, although prices were low, in 1908 the customary exportation to the United States did not take place, and other countries were not such large buyers as formerly. On the other hand, American competition was less acute. In consequence of the high duties imposed by certain other States the exportation of paper to them from Germany is now only possible at a sacrifice. During the past year the German paper makers reduced their prices, while the consumers refrained as far as possible from buying. The position of the makers was rendered still more difficult by the fact that the cellulose factories have taken more than ever to manufacture papers of all kinds. With the exception of the cartell of the manufacturers of printing paper, and of a few local groups, there is free competition. Consequently the cheaper sorts of paper intended for the home and foreign markets are only manufactured in large quantities by the large factories provided with the latest machinery, while the smaller factories either confine their activity to limited areas, or produce specialities for which they have exceptional facilities. The cost of wood pulp and cellulose fell only slightly during 1908, and the price of coal did not fall until after the end of the year. Business in rags was more favourable, for American buyers were less active than in former years, but this class of raw material will probably become dearer again so soon as the paper industry in the United States regains its normal activity. The price of kaolin is maintained by a syndicate, which endeavours to make the terms of delivery more and more unfavourable to the buyer. It is estimated that the average profits of the German paper manufacturing companies during 1908 amounted to 3·87 per cent.

PATENTS.

Old papers; Process for converting — into pulp for re-manufacture. L. Heitz. Fr. Pat. 397,576, Nov. 19, 1908.

Old printed papers are introduced together with a bleaching solution into a vertical cylinder provided with a

knading mechanism. The papers are then reduced to a pulp and bleached simultaneously. The bleaching liquor is allowed to drain away through a wire sieve at the bottom and is replaced by a stream of water at the top, the stirring mechanism being kept in motion until the pulp is sufficiently washed. The latter is then either used directly for the manufacture of paper or is pressed as half-stuff.—J. F. B.

"Soluble cellulose": *Process for preparation of* —. P. Marino, London. Eng. Pat. 7430, Apr. 3, 1908.

ORDINARY pyroxylin is introduced into a mixture of alcoholic solutions containing about 10 per cent. (of the weight of the pyroxylin) of each of the following substances: manganese chloride, ferric sulphate, and sodium ethyl sulphate. The solution is diluted with ether or other solvent of pyroxylin, and the pyroxylin is dissolved. A saturated solution of freshly precipitated ammonium magnesium phosphate is separately prepared in a quantity of sulphuric, phosphoric, or other mineral acid equivalent to about 10 per cent. of that of the solvent used with the pyroxylin. The two solutions are mixed and heated at 25° C. for 12 hours. The "soluble cellulose," which separates on cooling, is drained, washed and dried. The mother liquors are collected separately, and after dilution with spirit and neutralisation of the mineral acid, they may be utilised for rendering wood or fabrics non-inflammable.—J. F. B.

Cellulose acetate; Manufacture of moulds and matrices from —. H. B. Manissadjian. Fr. Pat. 397,429, Dec. 15, 1908.

CELLULOSE acetate is converted into a plastic mass by means of a solvent, and the mass is incorporated with softening agents which, according to their proportions, modify the softening temperature of the product to any desired degree, according to whether it is intended to serve as a mould or a matrix. Mineral filling agents may also be added. The plastic mass is composed of 40 parts of cellulose acetate and 80—100 parts of a volatile solvent, such as ethyl acetate, chloroform, acetone or alcohol. The softening agents consist of 5—20 per cent. of castor oil, calculated on the weight of the solution, about an equal proportion of a sulphophenic derivative of a halogen and 10—15 parts of glycerol acetate.—J. F. B.

Plastic mass [from acetylcellulose]; Process for the preparation of a —. F. Bume. Ger. Pat. 210,519, Aug. 25, 1907.

ACETYLCELLULOSE is mixed with camphor or a camphor substitute, then with a solvent (chloroform, acetone, ethyl acetate) and next with a precipitant (water, benzene, alcohol, etc.) miscible with the solvent; or the solvent and precipitant may be added together. The semi-solid plastic mass thus obtained can be moulded in the cold or it may be rolled on to a suitable support. It is not adhesive, and rapidly hardens. A. S.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Alkaloid; New — from the bark of *Pseudocinchona Africana* (Rubiaceæ). E. Fournieu. Compt. rend., 1909, 148, 1770—1772. (See this J., 1909, 671.)

FROM the bark of *Pseudocinchona Africana*, a native of the Ivory Coast, the author has isolated an optically active crystalline alkaloid, $C_{21}H_{26}N_2O_3$, and another which is optically inactive and has not been crystallised, though its crystalline hydrochloride has been obtained pure. To prepare these, the powdered bark is extracted with very dilute cold sulphuric acid, and sodium carbonate is added to the extract; the precipitate, thus obtained, is dried and boiled with ethyl acetate, and the filtered solution is concentrated and precipitated with ether. The crystalline magma resulting being recrystallised several times from alcohol: the amorphous alkaloid is

contained in the ethereal mother liquor. The crystalline alkaloid separates from absolute alcohol in colourless anhydrous tablets which become coloured on exposure to light; it is alkaline to litmus and almost insoluble in water and ether, but soluble in boiling chloroform; its formula is identical with that of quabracine, which resembles in many respects, though, unlike this, it is levorotatory ($[\alpha]_D$ at 23° C. = -125°). It combines with one equivalent of acids to give well-defined salts which may be crystallised from alcohol; the hydrochloride, sulphate, tartrate, and methiodide are described. With strong sulphuric acid it gives a colourless solution becoming slightly brown, and a crystal of potassium bichromate leaves a deep blue streak in this solution. —F. SODS.

pseudo-Morphine. G. Bertrand and V. I. Moyer. Comp. rend., 1909, 148, 1681—1683.

EBULLIOSCOPIC or cryoscopic methods cannot be used to determine the molecular weight of ψ -morphine because the base forms molecular aggregates in solution. The solution of the hydrochloride in water, however, contains two molecules of the acid to one of the base, and an examination of the acetyl derivative confirms the conclusion drawn from this observation, namely, that ψ -morphine has the formula, $C_{21}H_{26}O_6N_2$, and is therefore to be regarded as being formed from two molecules of morphine, each of which loses one atom of hydrogen. As the two morphine residues retain their phenolic hydroxyl group it is probable that they are linked together by two carbon atoms.—J. C. C.

Cotarnine; Synthesis of substances allied to —. A. H. Salway. Chem. Soc. Trans., 1909, 95, 1204—1220.

THE author prepared myristicin aldehyde, by converting myristicin into isomyristicin, and oxidising the latter with permanganate. When the aldehyde is treated with sodium and ethyl acetate, and the product hydrolysed, 3-methoxy-4:5-methylenedioxyinnamic acid is produced. This acid crystallises from acetic acid and melts with decomposition at 228° C. β -3-Methoxy-4:5-methylenedioxypropionic acid was obtained by reducing the innamic acid derivative in alkaline solution with sodium amalgam; it crystallises from benzene and alcohol in hard colourless nodules melting at 124°—125° C. Treatment with phosphoric oxide converts this acid into methoxymethylenedioxy- α -hydrindone, which melts at 141°—142° C. after crystallising from alcohol. Myristicinylideneaminoacetal was prepared by the condensation of aminoacetal and myristicin aldehyde; it is a colourless oil boiling at 234° C. at 15 mm., and 244° C. at 25 mm. When this substance is reduced with aluminium amalgam, two compounds are produced, a solid basic substance, $C_{20}H_{41}O_{16}N_2$, melting at 128° C. and a colourless oil, myristicinylaminoacetal, $C_{15}H_{23}O_8N$, boiling at 247° C. at 27 mm. When methoxymethylenedioxyinnamic acid is treated with nitric acid, the carboxyl grouping is replaced by a nitro grouping, with the result that ω -2(6)-dinitro-3-methoxy-4:5-methylenedioxystyrene is produced, which melts at 148° C. 2(6)-Nitro-3-methoxy-4:5-methylenedioxyinnamic acid was prepared from nitromyristicin aldehyde by the action of acetic anhydride and sodium acetate. The free acid decomposes at 266° C., and the methyl ester melts at 192° C. and can be reduced by stannous chloride to the corresponding amino derivative, which forms yellow needles melting at 153° C. When this base is warmed with dilute acid, hydrolysis and condensation occur, with the formation of 2-keto-8(5)-methoxy-6:7-methylenedioxy-1:2-dihydroquinoline, melting at 181°—182° C. The O-methyl ether of this dihydroquinoline melts at 113° C., whilst the N-methyl ether melts at 179° C. When the latter substance is reduced with sodium amalgam, two atoms of hydrogen are introduced and there is produced oxyisocotarnine, or 2-keto-8(5)-methoxy-6:7-methylenedioxy-1-methyl-1:2:3:4-tetrahydroquinoline, $C_{12}H_{13}O_4N$, which is a feebly basic substance melting at 113° C. —F. SODS.

hydrastine, hydrastinine, and narcotine; New reactions or ——. A. Labat. Bull. Soc. Chim., 1909, 5, 742—743.

HYDRASTINE (1:300), and hydrastinine (1:100) are dissolved in alcohol; narcotine (1:100) is dissolved in pure sulphuric acid (1:10). One-tenth of a c.c. of the alkaloid solution is added to 2 c.c. of pure sulphuric acid (sp. gr. 1.84), followed by the addition of 0.1 c.c. of a solution of certain phenolic substances. On warming the mixture on a water-bath, intense colorations develop. With a solution of gallic acid (1:20) there is a strong emerald green coloration, passing into a blue. If a solution of guaiacol or catechol (1:20) is used, a red tint is produced, which on warming deepens and changes to violet. If a solution of morphine (1:50) is used, there is a violet tint.—F. SHDN.

Opianic acid; New reactions for —, and their use for detecting hydrastine and narcotine. A. Labat. Bull. Soc. Chim., 1909, 5, 743—745.

A 10 per cent solution of opianic acid in alcohol is prepared, and 0.1 c.c. is added to 2 c.c. of sulphuric acid (sp. gr. 1.84) followed by the addition of 0.1 c.c. of a solution of a phenolic substance. With gallic acid there is a blue colour, which fades, on warming, to a dull brown. With guaiacol, there is a red colour, changing to intense blue on heating. α -Naphthol gives gooseberry-red colour, whilst β -naphthol produces a wine-red. With codeine in alcohol (1:20) there is a light colour, slowly changing to blue on warming. Diethylnaphthol in alcohol (1:40) produces a strong light colour fading when warmed. If hydrastine or narcotine is oxidised in acid solution with permanganate, opianic acid is produced. When alcohol is added, the opianic acid in the solution can be detected by the above tests.—F. SHDN.

Essential oils; Constituents of —. Carlina oxide and some attempts at its synthesis. F. W. Semmler and E. Ascher. Ber., 1909, 42, 2355—2360.

The authors have prepared several compounds showing it in all probability carlina-oxide (this J., 1906, 281) is a 1-phenyl-3- α -furyl-allene. Furalacetophenone (phenyl-1- α -furyl-propene-2-one-1) was prepared by the condensation of acetophenone and furfural in the presence of sodium ethoxide. It boils at 181°—182° C. at 9 mm., and has the sp. gr. 1.15 at 17°/4° C. When reduced with sodium and alcohol, 1-phenyl-3- α -furyl-propane is formed which boils at 135° C. at 10 mm., and has the sp. gr. 1.007 at 20°/4° C., and n_D^{20} = 1.530. It is identical with the tetrahydrocarlina-oxide produced by the reduction of carlina-oxide. During the reduction of furalacetophenone as described above, phenyl-1- α -furyl-propanol, $C_{13}H_{14}O_2$, is produced in considerable quantity. This boils at 168°—170° C. at 12 mm., and has the sp. gr. 1.10 at 20°/4° C., and n_D^{20} = 1.553. When heated with phosphorus pentachloride, it forms a chloride, $H_2CHCl.CH_2.CH_2.C_6H_5O$, which boils at 154° C. at 11 mm., and has the sp. gr. 1.13 at 18°/4° C., and n_D^{18} = 1.552. When boiled with a solution of potassium dioxides in ethyl alcohol, the chlorine atom is replaced by an ethoxyl grouping. The compound, $C_{12}H_{18}O_2$, thus produced, boils at 145°—147° C. at 11 mm., and has the sp. gr. 1.055 at 20°/4° C., and n_D^{20} = 1.545. Hydrogen chloride can be removed by heating the above chloride at 170°—180° C. with sodium acetate and acetic acid in a sealed tube. In this way, phenyl-1- α -furyl-3-propene-1, dihydrocarlina-oxide, $C_9H_8.CH:CH.CH_2.C_6H_5O$ is produced. This substance boils at 146.5°—147° C. at 11 mm., and has the sp. gr. 1.029 at 20°/4° C., and n_D^{20} = 1.552. Benzoylfuroylmethane, $C_{15}H_{12}.CO.CH_2.CO.C_6H_5O$, is prepared by a method similar to that employed by Claisen in the preparation of benzoylacetophenone. The diketone obtained by the authors melted at 69° C., and boiled at 194°—196° C. at 11 mm. The monoxime melts at 137° C., and the dioxime at 168° C. When heated with sodium amalgam in dilute acetic acid, a acetate, $C_{12}H_{14}.O_3(CH_3.CO)_2$, is produced, which melts at 149° C.—F. SHDN.

Antipyrine and cryogenin; Vanillin as a reagent for —. Its application for the detection of antipyrine in pyramidone. C. Primot. Bull. des Sc. Pharmacolog., 1909, 270. Pharm. J., 1909, 83, 9.

VANILLIN gives an extremely delicate reaction with antipyrine. The reagent is prepared thus:—Vanillin, 1 gm.; hydrochloric acid, diluted with an equal volume of water, 6 grms.; alcohol, 95 per cent., 100 grms. A very small crystal of antipyrine is placed in the bottom of a round-bottomed capsule, and about 2 c.c. of the reagent is poured on to it, and the whole evaporated on the water-bath. There is formed first a deep orange ring, and then a deposit of the same colour on the bottom of the capsule. As pyramidone does not react in this way, the reaction serves to show its adulteration with antipyrine. Cryogenin gives with the same reagent, a yellow-green tint under the same conditions, and the reaction is equally delicate.

Benzene sulphonic chloride; Preparation of —. R. Pummerer. Ber., 1909, 42, 2274—2275.

Using the process described in a previous paper (this J., 1909, 672), the author finds that a slightly higher temperature is favourable to the production of good yields of benzene sulphonic chloride. For instance, 100 grms. of benzene were allowed to drop during 1½—2 hours into 250 c.c. of chlorosulphonic acid, and the mixture allowed to stand for 20 hours at 15°—20° C. By distillation a yield of 159 grms. of benzene sulphonic chloride was obtained. Another mixture was allowed to stand for 3 hours at 25°—30° C., when 155 grms. of the sulphonic chloride were produced.—F. SHDN.

Organic acids; Action of sulphur monochloride on salts of —: a convenient method of preparing anhydrides. W. S. Denham. Chem. Soc. Trans., 1909, 95, 1235—1241.

WHEN sulphur monochloride is brought into contact with the sodium or silver salts of many monobasic acids in the presence of solvents such as light petroleum, ether, or benzene, unstable derivatives of the acids are produced in which sulphur replaces the hydrogen of the hydroxyl group. These compounds readily decompose into sulphur dioxide, sulphur, and the acid anhydrides, according, in the case of sodium benzoate, to the following equations:

Benzoic, the isomeric toluic, acetic, phenylacetic and propionic acids all behave similarly. The silver salts of salicylic, ethylsalicylic and *o*-nitrobenzoic acids appear to behave in a more complex manner. The salts of succinic and the phthalic acids react readily yielding their anhydrides without the formation of intermediate compounds. The quantitative and simple nature of these reactions affords a rapid and convenient method of preparing the anhydrides of the acids.—A. H. C.

Phenols; New method for the alkylation of —. A. Einhorn. Ber., 1909, 42, 2237—2238.

MIXED carbonic acid esters of phenols, which contain an alkyl grouping, lose carbon dioxide on heating and form alkylated phenols:—

The diethylaminoethyl ester of guaiacolecarbonic acid when distilled in a vacuum yields diethylaminoethyl-guaiacol. Other esters, for instance, the methyl ester of guaiacolecarbonic acid, and the methyl ester of β -naphtholecarbonic acid, require many hours' boiling under atmospheric pressure to effect their decomposition. The same reaction takes place with mixed carbonic acid esters of the following substances, resorcinol, ethyl alcohol, thymol, eugenol, isoeugenol, salicylic acid, and *p*-hydroxybenzoic acid. When the ethyl ester of guaiacolecarbonic acid is heated for several days, the principal product of the reaction is ethylguaiacol with some guaiacol carbonate.—F. SHDN.

Methyl alcohol; Action of metallic oxides on —. P. Sabatier and A. Mailhe. *Compt. rend.*, 1909, 148, 1734—1736.

PREVIOUS work upon the action of metallic oxides on primary alcohols below 400 C. (this J., 1908, 767, 831) has been extended to methyl alcohol. The reduction of the various oxides was found to be analogous to that with other alcohols, but the catalytic decomposition of the alcohol differs, in that, the formation of an ethylenic hydrocarbon being impossible, only methyl ether is produced by dehydration, and the formaldehyde, resulting from dehydrogenation (catalytic or otherwise), commences to decompose at 280 C. into hydrogen and carbon monoxide, being almost completely destroyed at 350 C. With alumina, thoria, and titanium oxide, dehydration takes place, almost to the exclusion of aldehyde formation; chromic oxide and the blue oxide of tungsten give both methyl ether and formaldehyde and its decomposition products; and with most other non-reducible oxides, and some oxides which are slowly reduced, the predominating effect is that of reduction of the alcohol, much carbon monoxide and hydrogen being produced; stannous oxide is specially active. The efficiency of each oxide is largely dependent on its method of preparation.—F. SODN.

Alcohols; Catalytic action of metallic salts in the decomposition of —. Chavanne. *Bull. Soc. Chim. Belg.*, 1909, 23, 267.

THE sulphates of barium, magnesium, aluminium, chromium, manganese, nickel, cobalt and copper have a dehydrating action on alcohols at high temperatures and, with ethyl alcohol, yield ether and ethylene. Experiments made at temperatures of 250, 300 and 350° C. showed that the quantity of ethylene produced increases as the temperature is increased, whilst the quantity of ether increases with the temperature at first, but passes through a maximum point and decreases again when the temperature is further raised. The sulphates of zinc and cadmium have a dehydrogenising action; they yield aldehydes. The sulphates of the alkali metals have no action. The phosphates appear to behave similarly to the sulphates; ethyl ether is split up into ethylene and water under the action of the same catalysts.—J. F. B.

Dimercuricammonium bromide. H. Gauduchon. *Compt. rend.*, 1909, 148, 1763—1765.

WHEN a solution of mercuric bromide, at about 80° C., is added to an excess of a cold solution of ammonia, the resulting precipitate, when thoroughly washed, proves to be the compound, $\text{NH}_2\text{Br} \cdot \text{Hg}_2\text{Br}_2$, but when ammonia is added to the hot mercuric bromide solution and the precipitate obtained is washed free from bromide, it is found to have the formula, $(\text{NH}_2\text{Br})_2 \cdot \text{HgBr}_2$. On treating this latter compound with hot ammonia, until ammonium bromide no longer appears in the washings, dimercuricammonium bromide, $\text{NH}_2\text{Br} \cdot \text{Hg}_2\text{Br}_2$, is formed. This is a canary-yellow crystalline body, which explodes on sudden heating, but decomposes, when heated slowly to about 100° C., to give a mixture of mercurous bromide and mercury; it does not become hydrated in the presence of moisture. These compounds should be dried at a low temperature and in the dark.—F. SODN.

Determining volatile acids in tobacco. Kissling. *See XXIII.*

Test for mercury. Jones. *See XXIII.*

PATENTS.

Camphor; Manufacture of sticks, tablets and filaments of —. Chem. Fab. vorm. E. Schering, Berlin. Eng. Pat. 1532, Jan. 21, 1909. Under Int. Conv., Feb. 6, 1908.

CAMPOR is manufactured in the form of sticks or filaments by forcing it through dies of any desired cross-section. Transparent tablets can be made from these sticks by pressure.—J. F. B.

p-Nitro- and p-aminobenzoic acid; Manufacture of p-n-propyl esters of —. F. Fritzsche und Co., Hamburg, Germany. Eng. Pat. 2020, Jan. 27, 1909. Under Int. Conv., Mar. 24, 1908.

CLAIM is made for two new products, the *n*-propyl ester of *p*-nitro- and *p*-aminobenzoic acid, and also for process of manufacturing them. The latter compound is anæsthetic and is stated to have a stronger action than the corresponding ethyl ester (anæsthesin) and *m*-aminophydroxybenzoic acid methyl-ester (new orthoform). It is prepared, either from *p*-aminobenzoic acid as *n*-propyl alcohol, or by reducing the *n*-propyl ester of *p*-nitrobenzoic acid, which is obtained by boiling together *n*-propyl alcohol and *p*-nitrobenzoic acid, in the presence of a dehydrating agent. For example:—(1). 5 parts *n*-propyl alcohol are boiled with 1 part of *p*-nitrobenzoic acid and 1 part of sulphuric acid (66° B.), until esterification is complete; the excess of alcohol is distilled off the sulphuric acid neutralised, and the insoluble *p*-nitrobenzoic acid *n*-propyl ester crystallised from alcohol; it forms colourless rhombic prisms (m. pt., 35° C.) which are very soluble in hot alcohol and slightly soluble in other organic solvents. The ester is reduced by boiling with 3 parts of hydrochloric acid and 1 part of tin, after the mixture, made alkaline with soda, is extracted with ether or benzene, from which the *p*-aminobenzoic acid *n*-propyl ester crystallises in rhombic prisms (m. p. 73°—74° C.), readily soluble in organic solvents and slightly soluble in water. (2). 1 part of *p*-aminobenzoic acid is boiled with 5 parts of *n*-propyl alcohol in the presence of sulphuric acid or a current of dry hydrochloric acid until a large proportion has been esterified, when the sulphuric or hydrochloric acid is neutralised, the excess of alcohol removed by distillation, and any free *p*-aminobenzoic acid washed out by dilute caustic soda, the remaining ester being crystallised from benzene.—F. SODN.

o-Sulphamidobenzoic acid; Manufacture of —. List, and Saccharin Fabrik Akt.-Ges., vorm. Fahlberg List, und Co., Salbke-Westerhüsen a/E., German. Eng. Pat. 8421, April 7, 1909.

ALKALI derivatives of saccharin are converted into alkali salts of *o*-sulphaminobenzoic acid by heating the mixture obtained by oxidising *o*-toluenesulphamide with potassium permanganate, with a small amount of alkali, under pressure to a high temperature. A solution of 100 kilos. of *o*-toluenesulphamide in 1000 litres of water, to which 1 kilos. of caustic soda solution (40° B.) have been added, is oxidised by 190 kilos. of potassium permanganate at 50°—70° C. The product is heated in an autoclave provided with a stirrer, for 6—8 hours at 160° C., and filtered, and the solution treated in the usual manner to recover the *o*-sulphaminobenzoic acid.—T. F. B.

Medicament [Terpene peroxide]; Process of producing —. W. D. Neel, Chicago, Ill., Assignor to T. Oxoline Co., Jersey City, N.J., and The Neel-Armstrong Co., Maine. U.S. Pat. 925,599, June 22, 1909.

AN inhalable medicament (terpene peroxide) is produced by treating a hydrocarbon oil of the terpene group, for instance eucalyptus oil, in the absence of water, with gaseous oxidising agent (ozone or ozonised air) capable of oxidising the hydrocarbon and causing evolution of fumes of the terpene peroxide.—A. S.

Chloroform; Preparation of — in a solid condition. C. J. Schleieh, Berlin. U.S. Pat. 925,658, June 2, 1909.

A SOLID medical preparation is obtained by mixing peptone with excess of chloroform and then allowing the excess to evaporate.—A. S.

Tobacco; Process and apparatus for de-nicotinising —. Soc. des Tabacs Désintoxiqués, Fr. Pat. 397,02 Dec. 2, 1908. Under Int. Conv., Dec. 11, 1907.

THE tobacco is extracted with a solution previously saturated with the soluble constituents of tobacco free from nicotine. The solution containing the nicotine is then drawn off, rendered alkaline with ammonia, and

conveyed to a tank which is divided into two parts by means of a partition. The alkaline solution is filled into the compartment until it is about three-quarters full, whilst a similarly saturated solution, acidified with either sulphuric acid or oxalic acid, is placed in the other compartment. Petroleum spirit is then added to each compartment, an aperture at the top of the partition allowing the petroleum spirit to pass from one compartment to the other. A stirring device is provided in each compartment and the nicotine removed from the alkaline solution by the petroleum spirit is extracted from the latter by the acid solution. The alkaline solution may then be used for extracting further quantities of tobacco. If sulphuric acid be used to acidify the solution, portions must be withdrawn and fresh solution added as the solution becomes saturated with nicotine salts; but if oxalic acid is employed, it is sufficient to remove the crystals of nicotine oxalate from time to time.—W. P. S.

Monohalogen-acetic esters from dihalogen-vinylethers: Process for preparing —. G. Imbert, and Consortium f. Elektrochemische Industrie. Ger. Pat. 210,502, May 27, 1908. Addition to Ger. Pat. 209,268, Nov. 4, 1906.

In the preparation of monohalogen acetic esters by heating halogenvinyl ethers with water (see Fr. Pat. 375,167, 1907; this J., 1907, 839), the reaction is accelerated by the presence of hydrochloric acid. The best method of carrying out the process is to heat the ether with concentrated hydrochloric acid, the two substances having about the same specific gravities. The yields are said to be very good.—T. F. B.

Nitro-compounds of nitriles of aromatic carboxylic acids and oxalic acid; Process for preparing —. Kalle und Co., A.-G. Ger. Pat. 210,563, Dec. 5, 1907.

NITROPHENYLPIRUVIC acid is readily converted into nitrobenzonitrile and oxalic acid by heating it at 60°–70° C. with a molecular proportion of nitrous acid; the simonitrobenzoylgyoxylic acid, which is formed as an intermediate product, is decomposed at about 80° C. to oxalic acid and nitrobenzonitrile. Homologues of nitrobenzonitrile may be obtained by similarly treating homologues of *o*-nitrophenylpyruvic acid.—T. F. B.

Glyoxylic acid, its esters and anide, and phenylglycine and its derivatives; Process for preparing — from oxalic acid by electrolytic reduction. Kinzlerberger und Co. Ger. Pat. 210,693, Aug. 14, 1904. Addition to Ger. Pat. 163,842, Sept. 10, 1903 (this J., 1906, 492).

In place of using lead cathodes for the electrolytic reduction of oxalic acid, cathodes of other metals insoluble in sulphuric acid, especially mercury cathodes, are employed; the strength, pressure, and duration of current must be varied according to the metal used and the product to be obtained. For instance, for the preparation of glyoxylic acid, oxalic acid dissolved in a 2.5 to 5 per cent. solution of sulphuric acid, is electrolysed in presence of lead anodes and mercury cathodes, by a current of 6.5 amps. (current density 3 amps. per sq. dm.) at 7.5 volts, at a temperature of 5° C.; the yields are said to reach 89–85 per cent. of theory.—T. F. B.

Chlorides and anhydrides of organic acids; Process for preparing —. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 210,805, Jan. 10, 1907.

In the action of sulphur dioxide, either in gaseous form or in solution, on the salts of organic acids, solid addition products are obtained; these are readily decomposed by chlorine, the chlorides and anhydrides of the acids being reduced, according to the amount of chlorine used. Thus, acetyl chloride is prepared by passing 7.1 parts of chlorine over 22–26 parts of the addition product of sodium acetate and sulphur dioxide, containing 6.4 parts of SO₂; the reaction is rendered smoother by diluting the solid with anhydrous salts of inorganic bases or with and.—T. F. B.

2,6-Dichloro- and 2,3,6-Trichlorotoluene-4-sulphonic chloride. Process for preparing a mixture of —. Anilinfarben- und Extract-Fabr. vorm. J. R. Geigy. Ger. Pat. 210,856, March 5, 1908.

p-TOLUENESULPHONIC chloride is treated with chlorine in presence of a suitable catalytic agent (e.g., antimony trichloride), at 70°–80° C., until the amount of chlorine absorbed corresponds to two atoms for each molecule of the sulphonic chloride. A mixture of 2,6-dichloro- and 2,3,6-trichloro-toluenesulphonic chlorides separates out on cooling, and can be converted into the corresponding sulphonic acids by saponification; the sulphonic acids can then be converted into the chlorinated hydrocarbons by heating with 80 per cent. sulphuric acid. On distilling the resulting mixture, the greater part passes over at 190°–200° C., and consists of 2,6-dichlorotoluene, whilst the 2,3,6-trichlorotoluene distils at 220°–230° C.

—T. F. B.

Magnesium phosphotartarate; Process for preparing —. K. Sorger. Ger. Pat. 210,857, June 23, 1908.

MAGNESIUM phosphotartarate is obtained by either of the following processes:—(1). Action of tartaric acid or magnesium hydrogen tartrate on magnesium phosphate; (2). action of phosphoric acid or magnesium hydrogen phosphate on magnesium tartrate; (3). decomposition of sodium phosphotartarate with magnesium oxide. The new salt is a white powder, sparingly soluble in water and dilute acids, and is said to be tasteless.—T. F. B.

Allophanic acid ester of castor oil; Process for preparing the —. Verein. Chindfabr. Zimmer und Co. Ger. Pat. 211,197, Dec. 28, 1907.

AN allophanic ester of castor oil, of the composition, C₅₇H₁₁₃O₁₀(CO.C₁₇H₃₃O.C₂O₂N₂H₃)₃, is obtained by treating castor oil with urea chloride, or by any other method for preparing allophanates. It is a white, tasteless, odourless powder, of m. pt. 61°–62° C., insoluble in water, sparingly soluble in cold alcohol, but readily soluble in hot alcohol.

—T. F. B.

Tetranitromethane from acetic anhydride and nitric anhydride; Process for preparing —. R. Schenck. Ger. Pats. 211,198, Jan. 28, 1908, and 211,199, June 23, 1908.

(1). ACETIC anhydride is added, in small quantities at a time, to nitric anhydride, at temperatures below 40° C., preferably in presence of a diluent. Concentrated nitric acid may be utilised as the source of the nitric anhydride, decomposition being effected by phosphoric anhydride or other suitable agent. After all the acetic anhydride has been added, the mixture is allowed to stand for some time at a temperature below 40° C., and the tetranitromethane recovered by fractional distillation. (2). Nitrogen tetroxide, N₂O₄, is employed as diluent for the nitric anhydride. 120 grms. of acetic anhydride are gradually added to a mixture of 155 grms. of nitric anhydride and 75 grms. of nitrogen tetroxide, the temperature being maintained at 30° C.; the tetranitromethane can then be recovered by distillation or addition of water.—T. F. B.

Lacilin, free from bitter alkaloids, from the seeds of lupines and other podded plants; Process for obtaining —. H. C. Buer, Cologne-Marienburg, Germany. Eng. Pat. 12,405, June 9, 1908.

SEE Ger. Pat. 200,253 of 1907; this J., 1908, 1131.—T. F. B.

1-Aryl-2,4-dialkylhalogenmethylpyrazolones; Manufacture of —. O. Murray, London. From Farbwerke vorm. Meister, Lucius, und Brüning, Höchst or Mainz, Germany. Eng. Pat. 20,377, Sept. 28, 1908.

SEE Ger. Pats. 206,637 and 208,593; this J., 1909, 328, 491.—T. F. B.

Polychlorandine derivative. C. Schrambe and E. Laudien. Assignors to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U.S. Pat. 926,023, June 22, 1909.

SEE Eng. Pat. 8077 of 1906; this J., 1906, 608.—T. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photographic prints; Preparation of — by means of basic dyestuffs. R. Namias. Seventh Int. Congr. Appl. Chem., London, 1909.

SILVER prints are bleached by immersion in a solution of lead ferriocyanide, whereby the image is converted into one of ferrocyanides of lead and silver; the silver ferrocyanide is dissolved out by means of a dilute solution of sodium thiosulphate, and the lead ferrocyanide is converted by means of sodium sulphate into lead sulphate, which is used as a mordant for basic dyestuffs, such as Auramine. The lead sulphate may finally be removed by means of concentrated sodium thiosulphate solution, when an image composed of the dyestuff alone remains.—T. F. B.

PATENT.

Photographic paper [prints]; Method of treating —. E. A. Cunningham. Ambridge, Pa. U.S. Pat. 917,418, April 6, 1909.

PHOTOGRAPHIC prints, such as those on ferroprussiate paper, which have been treated according to U.S. Pat. 895,970 of 1908 (this J., 1908, 959), are first subjected to the action of an alkali, such as ammonia, and then treated with a solution of potassium ferrocyanide and hydrochloric acid, whereby Prussian blue is formed; they are finally treated with an oxidising agent, such as potassium bichromate, washed, and dried.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Mine air; Impurities in — due to the firing of dynamite, and their effect upon health. S. Nauckhoff. Z. ges. Schiess- und Sprengstoffw., 1909, 4, 241–244.

THE author has investigated the question of the percentage of carbon monoxide present in the atmosphere of mines, after firing varying weights of charges of dynamite of different composition. For estimating the percentage of carbon monoxide, which is always small, he employed a 0.4 per cent. solution of palladium chloride. The yellow colour of this solution is discharged by carbon monoxide, and the method was standardised by employing volumes of air of from 250 c.c. to 1 litre, containing known quantities of carbon monoxide. The following gives some of the results obtained during standardising the method in this manner. Using 1 litre of air and 5 c.c. of palladium chloride solution, 0.01 per cent. of carbon monoxide produced only partial decolorisation after 4 to 5 hours. Carbon monoxide to the extent of 0.04 per cent. completely decolorised the solution after $\frac{1}{2}$ to 1 hour, whilst 0.1 per cent. brought about complete decolorisation at the expiration of 5 minutes. The explosives were fired in the drives in the mines at Grönge-berg, and samples of the mine air were collected in flasks varying from 250 c.c. to 1 litre in capacity. In each case, after passing the gas through sulphuric acid and caustic potash, its content of carbon monoxide was determined. The results obtained are shown in the following table, together with the calculated quantities of carbon monoxide, supposing complete combustion of the explosive to have taken place.

Express dynamite and weight used.	Carbon monoxide.	
	Found.	Calculated.
	Per cent.	Per cent.
No. 1 15.0 kilos.	0.025	0.015
No. 1 4.5 kilos.	0.01	0.008
No. 1 9.2 kilos.	0.02	0.009
No. 1 13.2 kilos.	0.02	0.013
No. 2 10.0 kilos.	trace	Nil
No. 2 12.5 kilos.	Nil	Nil
No. 3 7.7 kilos.	0.035	0.09
No. 3 16.0 kilos.	0.09	0.16
No. 2 4.0 kilos.		

In the case last recorded the miners found that they suffered from headache after several hours' working. Lange states that breathing air containing 0.2 to 0.3 per cent. of carbon monoxide produces serious symptoms in from $\frac{1}{2}$ to 1 hour. Air containing 0.05 to 0.10 per cent. produces little ill effect during the same period, whilst air containing 0.02 per cent. of carbon monoxide can be breathed for several hours with hardly any perceptible effect. Air which contains 4 per cent. of carbon dioxide produces difficulty in breathing. If the carbon dioxide content rises to about 10 per cent., serious trouble is experienced, although the after-effects are not necessarily dangerous. But in the experiments mentioned above the amount of carbon dioxide present in the mine air would be only about 0.5 per cent., which, allowing also for the nitrogen evolved from the explosive, would only mean a reduction of oxygen of about 1 per cent. The author points out that where, as in Sweden, it is customary to add from 5 to 10 per cent. of nitrobenzol for the purpose of lowering the freezing point of explosives intended for use in winter, a considerable amount of carbon monoxide would be produced. In view of the author's experiments and bearing in mind that a considerable number of cases of gas poisoning occur yearly in mines, the author suggests that the following possible conditions of work may be productive of an excess of carbon monoxide. The use of frozen explosives which do not fit the bore-hole, and consequently, produce a low charge density; the use of No. 4 detonators, which may not be sufficiently strong for the work; the presence of the paper wrapping on the cartridges, which would give rise to carbon monoxide, and the possibility of the reduction at high temperatures of carbon dioxide by coal dust in the mines.—G. W. McD.

PATENTS.

[Blasting] explosives. B. E. D. Kilburn. London. From C. Pieper, Berlin. Eng. Pat. 15,916, July 27, 1908.

THE patent relates to a new blasting explosive, composed of ammonium perchlorate, an alkali nitrate, and two hydrocarbons, of which one is a solid or liquid product of natural petroleum, substantially non-volatile at ordinary temperatures, while the other is a nitrated coal tar product. A suitable binding medium may be added, the explosive being used in the form of powder or otherwise. The perchlorate and nitrate are present in molecular proportion and the relative quantities of carbon and oxygen may be such that, as far as possible, complete combustion takes place. An example is given of a mixture containing paraffin wax 13 per cent., trinitrotoluene 14, ammonium perchlorate 42, and sodium nitrate 31 per cent. No residue is said to be left from these explosives, and, further, a low flame temperature is combined with considerable explosive power.—F. SOPS.

Gelatin dynamite; Machine for packing explosive —

W. J. Donaldson, Paulsboro, N.J., Assignor to T. E. L. Du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 914,396, March 9, 1909.

A GELATINOUS explosive is fed from a cylindrical hopper by means of a screw through openings, arranged with nozzles, into cartridge cases held by a carrier. The nozzles project into the cases during the process of filling. On top of the cylinder is a conical hopper slightly contracted at the mouth. Blades, set at an angle, are fixed to the shaft where it passes through the conical hopper, so as to feed the explosive into the cylinder, from which it is forced by means of the screw through the nozzles into the cartridge cases. The feed of the cylinder is thus constant, and regulated by the screw in the cylinder itself. The holder for the cases is supported on a piston in an air cylinder which descends during the filling of the cases. When the holder descends to a point corresponding to the filled cartridge case, an indicating device, such as a whistle, is brought into play so that the time at which the case is filled is accurately determined. The feed screw is then stopped. This automatically results in the removal of the case holder, containing the filled cartridges, which is replaced by another holder of empty cases.—G. W. McD.

Donating compounds for cartridges; Use of manganese dioxide in —. Soc. Française des Munitions de Chasse, de Tir et de Guerre. Fr. Pat. 397,253, Nov. 30, 1908.

The use of manganese dioxide in detonating compounds claimed in order to produce an explosive which is not liable to premature explosion or miss-firing.—W. P. S.

nitroglycerin; Process for purifying —. C. Claessen. Ger. Pat. 210,990, July 30, 1907.

NITROGLYCERIN is kept for two hours in an atmosphere containing 75–80 per cent. of moisture, or is mixed with 50 per cent. of water; the mixture is absorbed by selguhr, and kept cool for some time, when a hydrate formed, corresponding to the formula,

can be obtained pure by recrystallisation from ether, when its melting point is 25° C. By dehydrating a desiccator or by a short heating at 40 C., it loses water and pure liquid dinitroglycerin is obtained.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Extraction of liquids with ether; Apparatus for —. A. H. Fiske, Amer. Chem. J., 1909, 41, 510–515.

The apparatus shown in the diagram is claimed to be of simpler construction and more efficient than any previously described. It consists of a flask, A, which is heated below a reflux condenser, B, to the lower part of which is attached, by means of rubber tubing, a trap, C, consisting of a small bulb with a side tube. The liquid to be extracted is placed in the flask, D, which has a capacity of about 500 c.c., and the condensed solvent passes from the trap, C, to the bottom of this flask. Thence it rises through the liquid, and runs back through the side tube of D, into the distilling flask, A, to be distilled again. The extraction flask is also fitted with

a siphon tube and a funnel so that its contents can be withdrawn or renewed without taking the apparatus to pieces. Comparative experiments showed that the extraction of succinic acid from large quantities of water

by means of ether in this apparatus was four times as rapid as in van Rijn's apparatus, this being due to the smaller capacity of the latter.—C. A. M.

PATENT.

Combustible gases; Method and apparatus for determining the calorific power of —. P. Lemoult et Soc. Anon. les Etablissements Poulsen Frères. First Addition, dated Dec. 1, 1908, to Fr. Pat. 385,726, Dec. 3, 1907.

THE Addition refers to modifications in the apparatus only, the method of working already described (this J., 1908, 27, 646) being unchanged. In the modified apparatus, the combustion or explosion is performed in a separate vessel, and a special glass sampling tube has also been added.—W. E. F. P.

INORGANIC—QUALITATIVE.

Mercury; New test for —. P. W. Jones. Proc. Roy. Soc. Queensland, 21, 49.

WHEN mercury is rubbed on aluminium in the presence of a little caustic alkali, an amalgam is formed, the bright surface of which in a moist atmosphere soon becomes covered with concretions of alumina. For a toxicological test, the sample is boiled with copper and platinum as in Reinsch's method, and the copper after washing and drying, is heated to dull redness for a few minutes and then let cool, in a tube closed with an aluminium plate. The latter is then rubbed with a wash leather moistened with a drop of caustic alkali, and allowed to stand for a few minutes in a moist atmosphere, when characteristic growths of alumina will be seen if mercury be present. 0.002 grain can be detected in viscera. In assaying, 0.5–1 gm. of the finely ground ore is mixed with an equal bulk of lime and a little reduced iron, and heated to dull redness in a small tube closed by a piece of aluminium. The latter is kept cool by means of a few drops of water.

INORGANIC—QUANTITATIVE.

Iron alum as a standard in volumetric analysis. De Koninck. Bull. Soc. Chim. Belg., 1909, 23, 261–262.

IRON ammonia alum is purified by crystallisation, the crystals are drained, sifted, spread for half an hour on filter paper and bottled whilst still slightly moist. Under these conditions the crystals may be preserved indefinitely. On exposure to air iron alum loses three-fourths of its water of crystallisation, and after several weeks it is converted into a white pulverulent substance having a composition corresponding to the formula, $(NH_4)_2Fe_2(SO_4)_3 \cdot 6H_2O$. This product is stable, very sparingly soluble in cold water, but soluble in hot water with reproduction of the alum. The efflorescence of iron alum is slow; crystals may be left for 45 minutes on the pan of the open balance without losing weight. In order to obtain a known weight of the normal alum, a portion of the moist crystals is tared on the balance, the front of the case being left open. After a short time the crystals will cease to lose weight, and the weight will remain constant for 15–20 minutes; at this stage the required weight of the alum may be adjusted with certainty.—J. F. B.

Solid solution; contamination of barium sulphate precipitates with aluminium. H. J. M. Creighton. Z. anorg. Chem., 1909, 63, 53–58.

WHEN a solution of ammonium sulphate, containing a little hydrochloric acid and a fixed amount of aluminium chloride, is precipitated with a slight excess of barium chloride and the mixture is heated for some hours, the weight of aluminium contaminating the precipitated barium sulphate is found to be proportional to the weight of ammonium sulphate present. If, however, this weight be kept constant and that of the aluminium chloride allowed to vary, the weight of co-precipitated aluminium increases with that of the aluminium present, up to a maximum, and then becomes constant. The author interprets these facts to mean that a solid solution of the

aluminium salt in barium sulphate is formed, which, in the second group of experiments, becomes saturated at a certain concentration.—F. SODX.

Iron: Determination of — by permanganate in the presence of hydrogen chloride. J. A. N. Friend. *Chem. Soc. Trans.*, 1909, **95**, 1228—1235.

Ferrous sulphate dissolved in water with just sufficient sulphuric acid to prevent the precipitation of basic salt, was titrated with $N/10$ solution of permanganate in the presence of varying quantities of hydrogen chloride and a little manganous sulphate. The author finds that accurate estimations of ferrous iron, in the presence of hydrogen chloride, can be made, provided that the volume titrated does not exceed 200 c.c. and the manganous sulphate present is not less than 2 grms in this volume. (1), if the titration is performed slowly with constant shaking; (2), if the concentration of the hydrogen chloride does not exceed $N/4$.—A. H. C.

Iron: Determination of — by permanganate, in the presence of hydrochloric acid. G. C. Jones and J. H. Jeffery. *Analyst*, 1909, **34**, 306—316.

The authors recommend a modified Zimmermann-Reinhardt process of titration in which the following reagents are employed:—*Manganese solution*: prepared, according to Reinhardt's formula, by dissolving 200 grms. of crystallised manganese sulphate in 1000 c.c. of water, and adding to this a cooled mixture of 400 c.c. of concentrated sulphuric acid, 600 c.c. of water, and 1000 c.c. of phosphoric acid of sp. gr. 1.3. *Stannous chloride*: 50 grms. of the crystallised salt and 100 c.c. of concentrated hydrochloric acid made up to 1000 c.c. with water. *Mercuric chloride*: a cold, saturated solution. *Hydrochloric acid*: acid of sp. gr. 1.1, or about the strength which exhibits a constant boiling point. The slight oxidising power sometimes possessed by the manganese solution, when freshly prepared, may be easily determined and allowed for if necessary; but it has been found that this oxidising effect is unmeasurable when the solution is a week old. In the presence of hydrochloric acid, permanganate titrations give results which are a little too high, even when the manganese solution is employed; the authors find that the small error so introduced is a constant one, independent of the amount of iron present, and therefore easily allowed for. The titration is carried out as follows:—The iron solution (in hydrochloric acid of 1.1 sp. gr.) is reduced with the smallest possible excess of stannous chloride, and 10 c.c. of mercuric chloride are added to the cold solution, the mixture being then allowed to stand for ten minutes to ensure the complete conversion of the stannous salt to the stannic condition, no appreciable oxidation of the reduced iron occurring in the meantime. A quantity of tap-water, which may vary between 400 and 1000 c.c. without appreciable effect on the titration, is then mixed, in a capacious bowl, with a volume of the manganese solution equal to that of the hydrochloric acid present in the assay, and the mixture tinted with permanganate, of which one drop should suffice. The ferrous solution is then transferred to the bowl, together with the rinsings of its containing vessel, and the permanganate added, drop by drop, with constant stirring, until the end point is reached. 0.1 c.c. is then deducted from the burette reading, and the amount of iron present is calculated by reference to the known titre of the permanganate, as determined by titration against a ferrous solution free from hydrochloric acid.—W. E. F. P.

Nickel and cobalt: Quantitative separation of — by the Rosenheim-Huldschinsky method. M. Pritze. *Chem. Zeit.*, 1909, **33**, 694.

The Rosenheim-Huldschinsky method (this J., 1901, 840) is based on the fact that cobalt-ammonium thiocyanate is soluble in a mixture of amyl alcohol and ether, whereas the corresponding nickel salt is insoluble. The metals can thus be separated by shaking an aqueous solution containing the two double salts with the organic solvent. The author has applied the method to alloys containing from 98—99 per cent. of nickel and 1—2 per cent. of cobalt,

but finds that varying small quantities of the nickel salt are always dissolved along with the cobalt salt. For the separation of these small quantities of nickel, precipitation with dimethylglyoxime (this J., 1907, 643, 121) proved more satisfactory than a second treatment with the organic solvent.—A. S.

Niobium in presence of tantalum: Volumetric method for the determination of —, and its application to the analysis of niobium minerals. C. E. Taylor. Dissertation, Columbia University, U.S.A.

The method proposed is based on the facts that if succinic acid be added to a solution of niobium and tantalum in strong sulphuric acid, the solution can then be largely diluted without the formation of any precipitate, and in the diluted solution the niobium can be determined by reduction with zinc and titration with permanganate without interference from the tantalum. From 0.2 to 1 gm. of the mineral is fused with 5—10 grms. of potassium bisulphate, the cooled melt is boiled with water and filtered through a rubber funnel. The insoluble matter is washed well with hot water, then with several portions (15 or 20 c.c.) of hot yellow ammonium sulphide, and afterward in succession with hot water, dilute sulphuric acid, and hot water. The white residue of silica and niobian and tantalic acids is dissolved off the filter by means of warm dilute hydrofluoric acid and the solution is mixed with 19 c.c. of concentrated sulphuric acid and evaporated until white fumes are copiously evolved, when a few c.c. more of sulphuric acid are added and the evaporation repeated. The solution is then allowed to cool, poured into cold water, and the whole diluted to about 500 c.c. boiled for a few minutes, and filtered. The insoluble matter is washed with boiling water, dried, ignited with a strong blast flame for 10 minutes and weighed. This gives the weight of the combined oxides of niobium and tantalum. The oxides are now fused with 5 grms. of potassium bisulphate, the melt is heated with 10 c.c. of concentrated sulphuric acid, and the clear solution transferred to a beaker, the crucible being rinsed out with 30 c.c. of concentrated sulphuric acid. The acid solution is allowed to cool, and 2 grms. of succinic acid added, followed by 20 c.c. of a saturated aqueous solution of succinic acid in a fine stream from a wash-bottle, the mixture being kept agitated. The solution is next diluted gradually to 200 c.c., being kept constantly agitated meanwhile, then heated to 75° C., and passed through a "reductor," 19 in. long by $\frac{3}{4}$ in. diam., filled with amalgamated zinc, prepared by shaking 600 grms. of 20—30 mesh C.P. zinc with an acid mercury solution (0.5 gm. of mercury dissolved in 25 c.c. of concentrated nitric acid and diluted to 250 c.c.), washing with water, then shaking with dilute sulphuric acid, and keeping under water until required for use. The reductor filled with zinc is prepared for use by passing through it 200 c.c. of 5 per cent. sulphuric acid heated to 75° C., and then filling it with 20 per cent. sulphuric acid also at 75° C. After passing the niobium solution through, 50 c.c. of 20 per cent. and 200 c.c. of 5 per cent. sulphuric acid are passed through. The reduced solution is then titrated with permanganate (1 c.c. of $N/10$ permanganate = 0.007052 gm. of niobium pentoxide). The reduction and titration are carried out in an atmosphere of carbon dioxide. The method is much more rapid and accurate than that of fractional crystallisation of the double fluorides of niobium and tantalum with potassium.—A. S.

ORGANIC—QUANTITATIVE.

Tobacco; Determination of volatile organic acids in — and the behaviour of oxalic acid. R. Kissling. Chem.-Zeit., 1909, 33, 719—720.

The author criticises statements made by Tóth in the description of a method for determining the volatile acids in tobacco (this J., 1908, 367). Malic, citric, and oxalic acids are not decomposed by a current of steam in presence of sulphuric or tartaric acid with formation of an acid salt, as stated by Tóth. Also, oxalic acid does not decompose on evaporation of its aqueous solutions on the water-bath, as stated by Tóth, but on evaporation to dryness, and further heating of the dry residue on the water-bath, it slowly sublimes. Tóth is also wrong in stating that it is necessary, in determining the amount of volatile acids by his method, to deduct the quantity of oxalic acid determined directly. The author is of opinion that a fully accurate knowledge of the various groups of acids in tobacco samples is obtained by his own method of determining the malic, citric, and oxalic acids, and then determining the volatile acids by the loss in weight of total acids, as indicated by Tóth's or any other method, evaporating once to dryness on the water-bath and stopping the evaporation as soon as no more water-vapour evolved. The loss of oxalic acid is then, according to the author, only very small, and he considers the results to be accurate enough for all practical purposes.—E. F.

BOARD OF AGRICULTURE AND FISHERIES. ANNUAL REPORT OF THE INTELLIGENCE DIVISION. PART I. PROCEEDINGS UNDER THE SALE OF FOOD AND DRUGS ACTS, 1875 TO 1907, THE MERCHANDISE MARKS ACTS, 1887 TO 1894, THE FERTILISERS AND FEEDING STUFFS ACT, 1906, AND THE BOARD OF AGRICULTURE ACT, 1889 SECTION 2, SUB-SECTION 3), FOR THE YEAR 1908. (Cd. 4688.) Wyman and Sons, Fetter Lane, E.C. Price 5½d.

It is a report describing the work accomplished by the Commercial Control Branch of the Intelligence Division of the Board of Agriculture, which was established early in 1908, and undertakes inquiries and correspondence as to the administration of the Sale of Food and Drugs Acts,

1875 to 1907; complaints relating to adulteration of articles of food affecting the interests of agriculture; the administration of the Fertilisers and Feeding Stuffs Act, 1906; prosecutions under the Merchandise Marks (Prosecutions) Act, 1894; and complaints as to rates and facilities for the carriage of agricultural produce by rail.

LABORATORY METHODS OF INORGANIC CHEMISTRY. By HEINRICH BILTZ and WILHELM BILTZ. Translated by WILLIAM T. HALL and ARTHUR A. BLANCHARD. John Wiley and Sons, New York, 1909. Price 12s. 6d. net. Chapman and Hall, Limited, London.

8vo volume, containing 244 pages of subject matter, with 27 illustrations, and an alphabetical index. The subject matter is arranged and classified in the following manner:—I. THE ELEMENTS. II. CHANGES OF CONDITION. III. SIMPLE COMPOUNDS. (i), Oxides. (ii), Hydrides. (iii), Acids, bases, and salts. IV. COMPOUNDS CONTAINING A COMPLEX NEGATIVE COMPONENT. (i), Compounds with homogenous complexes. (ii), Oxyacids and their salts. (iii), Thioacids and their salts. (iv), Complex halogen acids and their salts. Complex cyanogen compounds. (v), Nitrito acids and their salts. (vi), Condensed acids and their salts. (vii), Organo-complex compounds. V. COMPOUNDS CONTAINING A COMPLEX POSITIVE COMPONENT. (i), Ammonium compounds and substituted ammonium compounds. (ii), Metal-ammonia compounds. (iii), Hydrates. VI. COMPLEX NON-ELECTROLYTES. (i), Acid chlorides. (ii), Esters. (iii), Metal-organic compounds. VII. PREPARATION OF COMPOUNDS OF THE RARE ELEMENTS FROM THEIR MINERALS.

VERHALTEN DER WICHTIGSTEN SELTENEN ERDEN ZU REAGENTIEN. ZUM GEBRAUCH IM LABORATORIUM. Von Dr. Jos. v. PANAYEFF. Wilhelm Knapp's Verlag. Halle a. S. 1909. Price M. 3.60.

8vo volume, containing a preface and 83 pages of subject matter. The subject matter receives the following classification:—I. Introduction. Periodic system of the elements. II. Zirconium. III. Thorium. IV. Cerium. V. Didymium (Praseodymium and Neodymium). VI. Lanthanum. VII. Yttrium. VIII. Erbium. In the case of each of the metals named, the reactions according to the wet and dry methods respectively, are described. In the case of cerium, the reactions both of the cerous and ceric salts, are given.

JAHRBERICHT ÜBER DIE LEISTUNGEN DER CHEMISCHEN TECHNOLOGIE, MIT BESONDERER BERÜCKSICHTIGUNG DER ELEKTROCHEMIE UND GEWERBESTATISTIK FÜR DAS JAHR 1908. LIV. Jahrgang, oder Neue Folge, XXXIX. Jahrgang. Bearbeitet von Dr. FERDINAND FISCHER. (Jahrgang I. bis XXV. von R. v. WAGNER.) 2^{te}. Abteilung: Organische Teil. Otto Wigand's Verlagsbuchhandlung und Buchdruckerei m.b.H. Leipzig. 1909.

8vo volume, containing 576 pages of subject matter, notices of new books, alphabetical indexes of names of authors and patentees, and of subjects, and an index of German patents, in all filling 619 pages. I. MANUFACTURING CHEMICAL INDUSTRY. (a), Alcohol preparations, and organic acids. (b), Cyanogen compounds. (c), Aromatic compounds. (d), Newly patented dentists' remedies. (e), Etheral oils and odorants. (f), Indigo. (g), Dye-stuffs of the Benzene series. (h), Naphthalene- and anthracene dyestuffs. (i), Sulphur dyestuffs. (j), Azo-dyestuffs. (k), Other dyestuffs, and lakes, &c. II. CARBOHYDRATES, FOODSTUFFS. (a), Starches. Saccharification. (b), Beet sugar. (c), Cane sugar. (d), Flour and bread. (e), Milk, butter, cheese, &c. (f), Meat. (g), Other foodstuffs, &c. (h), Fodders. III. FERMENTATION INDUSTRY. (a), Yeast and fermentation. (b), Wine. (c), Beer. (d), Spirits. IV. TEXTILE FIBRES. DYEING. (a), Animal fibres. (b), Artificial silk, &c. (c), Vegetable textile fibres. (d), Bleaching, dyeing, printing, &c. (e), Paper. V. FURTHER ORGANIC CHEMICAL INDUSTRIES. (a) Fats, oils, and lubricants. (b), Fatty acids, soaps, glycerin. (c), Varnishes, paints, resins. (d), Caoutchouc. (e), Celluloid, &c. (f), Tanning industries. Gums, &c. (g), Wood preservation.

ANNUAL STATEMENT OF THE TRADE OF THE UNITED KINGDOM WITH FOREIGN COUNTRIES AND BRITISH POSSESSIONS, 1908. Volume I. [Cd. 4687.] Price 6s. Wyman and Sons, Fetter Lane, E.C.

THIS is the first volume of the statement of the overseas trade of the United Kingdom for the year 1908, and contains abstract tables showing the total imports and exports of every article which is separately enumerated in the official classification, as well as detailed tables showing the quantity and value of the imports and exports of each article from and to each country, figures being given in each case not only for the year 1908, but for each of the four preceding years. Statistics of the imports and exports of coin and bullion from and to each country are given in separate tables at the end of the volume.

Several alterations have been made in the classification of imports and exports. As regards imports, the headings for china and earthenware, dyestuffs and tanning substances, machinery, steel, &c., have been subdivided in greater detail than formerly. The statements of the domestic exports of chemicals, china, and earthenware, machinery, metals, and paper are, amongst others, shown in greater detail.

Patent List.

Where a complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

15,062. Parouty-Dupont and Muneret. Distilling apparatus. June 28.

15,304. Humphrey. Raising liquids by compressed gases. June 30.

15,506. James. Means for generating and collecting gases. July 3.

15,829. Bost. Manufacture of heat insulating material. July 7.

15,931. Mechan. Discharge aperture fittings of cyanide and other tanks. July 8.

COMPLETE SPECIFICATIONS ACCEPTED.

14,014 (1908). Thomlinson-Haas (F. Haas Ges.). Apparatus for treating materials with air or other gases or vapours for drying, bleaching, &c. July 7.

23,720 (1908). Resines. Process and apparatus for filtering liquids. July 14.

26,843 (1908). Lake (Reif). Manufacture of chemical products in granulated, powdered, flaked, or similar condition. July 7.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

15,078. Jones. Coke ovens.* June 28.

15,192 and 15,193. Soc. Franç. d'Incandescence par le Gaz. Manufacture of filaments for incandescent electric lamps. [Fr. Appl., July 18, 1908.]* June 29.

15,196. Epstein. Fuel for internal-combustion motors. June 29.

15,206. Weidl. Horizontal coke oven.* June 29.

15,280. Epstein. Fuel for internal-combustion motors. June 30.

15,496. Jahoda. Manufacture of metallic filaments for electric incandescent lamps. [Austrian Appl., May 10, 1909.]* July 2.

15,569. Cone. Manufacture of gas. [U.S. Appl., July 3, 1908.]* July 3.

15,643. Richards and Pringle. Apparatus for distilling coal and recovering the products. July 5.

15,647. Lessing. Manufacture of electric carbon. July 5.

15,661. Thomas. Gas producer.* July 5.

15,704. Craig. Manufacture of coke in closed oven. July 6.

15,867. Bourdos. Manufacture of filaments for electric lamps. July 7.

15,911. Palmer. Suction gas producers for bituminous fuel. July 7.

16,110. Barton and Renison. Manufacture of artificial fuel. July 10.

COMPLETE SPECIFICATIONS ACCEPTED.

14,169 (1908). Parker. Retorts for the destructive distillation of coal or other carbonaceous substance. July 14.

14,405 (1908). Berry. Suction gas producers. July 14.

14,483 (1908). Marietti. Soldering metallic filaments of electric lamps to their electrodes. July 14.

14,558 (1908). Justice (Coal Treating Co.). Facilitation or controlling combustion of fuel and preventing smoke. July 14.

23,726 (1908). British Thomson-Houston Co., and Newham. Manufacture of filaments for incandescent electric lamps. July 7.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

15,071. Lessing. Decomposing hydrocarbons. June 28.

15,497. Boyer, Cavaillon, and Barishac. Preparation of lubricating oils having a basis of castor oil and mineral oils. [Fr. Appl., July 3, 1908.]* July 2.

COMPLETE SPECIFICATION ACCEPTED.

14,169 (1908). Parker. See under II.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

15,088. Kalle und Co. Manufacture of tetrabrom indigo. [Ger. Appl., Aug. 1, 1908.]* June 28.

15,089. Inray (Meister, Lucius, und Brüning). Manufacture of a black monoazo dyestuff. June 28.

15,142. Wyler, and Levinstein, Ltd. Dyestuffs of the indigo series and the production thereof. June 29.

15,403. Bloxam (Act.-Ges. f. Anilinfabr.). Manufacture of substantive disazo dyestuffs. July 1.

15,625. Newton (Bayer und Co.). Manufacture of black sulphur colouring matter. July 5.

15,846 and 15,848. Newton (Bayer und Co.). Manufacture of dyestuffs of the anthracene series. July 7.

15,847. Newton (Bayer und Co.). Manufacture of azo dyestuffs. July 7.

COMPLETE SPECIFICATIONS ACCEPTED.

16,743 (1908). Ransford (Cassella und Co.). Manufacture of azo dyestuffs. July 7.

23,190 (1908). Merz. See under XIII A.

24,601 (1908). Newton (Bayer und Co.). Production of flavopurpurine. July 14.

3758 (1909). Meister, Lucius, und Brüning. Manufacture of dyestuffs. July 14.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS AND FIBRES.

APPLICATIONS.

15,306. Lilienfeld. See under XIX.

15,341. Bright and Bros., Ltd., and Oldroyd. Colouring yarn for making carpets and other fabrics.* July 1.

- 15,658. Stine. Treatment of silk.* July 5.
 15,674. Marshall. Apparatus for dyeing and similarly treating textile material on bobbins or the like. July 5.
 15,828. Schneider. Preparing wool or other animal fibre for mordanting, dyeing, or printing. [Addition to No. 6152 of 1907.] July 7.

COMPLETE SPECIFICATIONS ACCEPTED.

- 14,014 (1908). Thomlinson-Haas (F. Haas Ges.). *See under I.*
 14,143 and 28,149 (1908). Lecoq. Manufacture of threads and filaments of cellulose. July 7.
 19,157 and 19,158 (1908). Tetley and Clayton. Apparatus for making artificial silk and like filaments or threads. July 7.
 23,972 (1908). Newton (Bayer and Co.). Process of printing. July 14.
 25,097 (1908). Courtauld and Co., and Clayton. Apparatus for spinning threads of artificial silk. July 14.
 3196 (1909). Bouchat. Apparatus for removing the grease from and bleaching wool. July 14.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 15,423. Eckford. *See under XIII A.*
 15,611. Johnson (Badische Anilin und Soda Fabrik). Manufacture of compounds containing nitrogen. July 5.
 15,823. Hill. Production of soda crystals. July 7.
 15,931. Mehan. *See under I.*
 15,995. Serpek. Production of compounds of aluminium and nitrogen. [Addition to No. 13,579 of 1906. Ger. Appl., Sept. 22, 1908.]* July 8.
 15,996. Serpek. Production of aluminium nitride. *See under I.*
 15,997. Serpek. Production of ammonia from aluminium nitride. [Ger. Appl., July 15, 1908.]* July 8.
 16,053. De Bechi and Blythe. *See under X.*

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,792 (1908). Eberhard. Increasing the mobility and reactivity of water-glass. July 7.
 15,239 and 17,976 (1908). Poehin and Richardson. Manufacture of ferrie sulphate and cakes or slabs containing ferrie sulphate. July 14.
 24,345 (1908). Langlet. Production of phosphoric acid or substances containing phosphoric acid soluble in water or citrates, from phosphatic raw materials. July 7.
 612 (1909). Leese. Manufacture of magnesite in the form of impalpable paste and of calcined magnesite therefrom. July 7.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATION.

- 15,924. Carter. Muffle kilns for firing tiles, earthenware, &c. July 8.

COMPLETE SPECIFICATIONS ACCEPTED.

- 21,260 (1908). Salamon, Grace, and Exploration Co. Preparation of china clay. July 14.
 2490 (1909). Bloxam (Hoorickx and Hendel). Manufacture of silvered glass mirrors. July 7.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 15,161. Metzger. Manufacture of cement from blast furnace slag.* June 29.
 15,165. Metzger. Machines for treating blast furnace slag in making cement.* June 29.
 15,649. Backus. Manufacture of artificial stone.* July 5.
 16,132. Christie. Manufacture of clay.* July 10.

COMPLETE SPECIFICATIONS ACCEPTED.

- 14,336 (1908). Kelly. Manufacture of cement. July 7.
 15,100 (1908). Kathe. Rendering artificial stone, mortar, plaster, &c., waterproof, non-conducting, and sound proof. July 14.

X.—METALS AND METALLURGY.

APPLICATIONS.

- 15,105. Nielsen. Soldering aluminium. June 28.
 15,164 and 15,165. Metzger. *See under IX.*
 15,172. Lavington (McMiken). Metallurgical furnace for use with oil, gas, &c. June 29.
 15,183. Custer. Producing from foundry iron a metal having properties of high grade tool and high speed steel.* June 29.
 15,189. Durant and Sulman. Separation of zinc from its ores or compounds. June 29.
 15,215. Johnson. Extraction of gold and other metals from ores. June 29.
 15,384. Mackintosh. Alloys. July 1.
 15,469. Wolf. Separation of metalliferous material from ores or other matter. July 2.
 15,764. Simpson and Oviatt. Manufacture of iron and steel directly from iron ores. July 6.
 15,913. Wasserfuhr. Protection of iron and similar substances against atmospheric influences.* July 7.
 15,987. Reynolds. Manufacture or forging of steel. July 8.
 15,988. Reynolds. Manufacture of steel. July 8.
 15,989. Reynolds. Manufacture of crucible steel. July 8.
 16,051. Cowper-Coles. Rendering iron surfaces non-corrosive. July 9.
 16,053. De Bechi and Blythe. Dissolving impure tin or tin alloys to obtain tin or tin compounds. July 9.

COMPLETE SPECIFICATIONS ACCEPTED.

- 12,317 (1908). Levy-Mond. Recovery of products from lead fumes or waste metallic solutions or suspensions. July 14.
 13,715 (1908). Mason. *See under XI.*
 13,964 (1908). Witter. Recovery of zinc oxide from molten slags of lead and copper smelters. July 7.
 14,399 (1908). Schumacher. Manufacture of briquettes from blast furnace slag. July 14.
 1786 (1909). Boulton (Kroeschell Bros. Co.). Crucible furnaces. July 14.
 6276 (1909). Norddeutsche Affinerie A.-G. Refining gold or gold alloys. July 7.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATION.

- 15,960. Flood. Electrolytic cell. July 8.

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,715 (1908). Mason. Preventing oxidisable metals from rusting after they are electroplated. July 7.
 13,734 (1908). Cornaro. Electrodes and resistances for electric furnaces, radiators, lamps, &c. July 7.
 15,792 (1908). British Thomson-Houston Co. (General Electric Co.). Electrolytes for electrolytic cells. July 7.
 18,246 (1908). Hutton and Hutton. Electroplating and like processes. July 7.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS

APPLICATIONS.

- 15,246. Savril, Ltd., Irving, and Wilson. Washing compound or soap.* June 29.
 15,497. Boyer, Cavaillon, and Barishac. *See under III.*
 15,748. De Hempinne. Transforming oils into viscous products and manufacture of lubricating oils.* July 6.

- 15,900. Hewitt. Manufacture of soap. July 7.
 16,058. Markel, and Crosfield and Sons, Ltd. Conversion of unsaturated fatty acids or their glycerides into saturated compounds. [Addition to No. 1515 of 1903.] July 9.
 16,148. Wynberg. Recovery of waxes, fats, and oils.* July 10.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

APPLICATIONS.

- 15,423. Eckford. Manufacture of red lead. July 1.
 COMPLETE SPECIFICATION ACCEPTED.
 23,190 (1908). Merz. Preparation of azo pigments insoluble in oil. July 7.

(B.)—RESINS, VARNISHES.

COMPLETE SPECIFICATION ACCEPTED.

- 5709 (1909). Yaryan. Purification of rosin. July 7.

(C.)—INDIA-RUBBER.

APPLICATIONS.

- 15,299. Wallace and Morton. Artificial production of india-rubber or caoutchouc. June 30.
 15,419. Walter. Quantitative recovery of rubber solvents used in manufacture. July 1.

XIV.—TANNING, LEATHER, GLUE, SIZE, &c.

APPLICATIONS.

- 15,028. Browning and Golder. *See under XVIII.A.*
 15,933. Mansfield Shoe Co., and Royce. Leather substitute. June 28.
 15,284. Silberrad. Dressing hides or leather. June 30.
 16,087. Lauro. Tanning apparatus.* July 9.

XV.—MANURES, &c.

APPLICATIONS.

- 15,093. Thompson (Van der Kolk.) *See under XVI.*
 15,594. Hughes. Manufacture of soluble or precipitated phosphatic manures. July 5.

COMPLETE SPECIFICATION ACCEPTED.

- 24,345 (1908). Langlet. *See under VII.*

XVI.—SUGAR, STARCH, GUM, &c.

APPLICATIONS.

- 15,092. Thompson (Van der Kolk). Furnaces for disposing of bagasse and molasses. June 28.
 15,093. Thompson (Van der Kolk). Utilisation of waste substances in cane plantations and manufacture of manure therefrom.* June 28.

COMPLETE SPECIFICATION ACCEPTED.

- 17,961 (1908). Ephraim. Gum and process of extracting same. July 7.

XVII.—BREWING, WINES, SPIRITS, &c.

APPLICATIONS.

- 15,278. Porteus. Treatment of malt for mashing purposes. June 30.
 15,407. Moritz. Brewing. July 1.
 15,499. Hewitt. Aleoholic fermentation. July 2.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

- 14,998. Kunick. Reconstitution of dried milk or cream to the liquid state. June 28.
 15,028. Browning and Golder. Machinery for the manufacture of casein. June 28.
 16,133. Loring. Treatment of flour. [Addition to No. 12,780 of 1908.] July 10.

COMPLETE SPECIFICATIONS ACCEPTED.

- 14,249 (1908). Slavoff. Preparation of coagulate milk. July 14.
 15,474 (1908). Quine. Cereal products. July 14.

(B.)—SANITATION; WATER PURIFICATION.

APPLICATIONS.

- 15,079. Hogermann and Wellensiek. Clarifying and utilising municipal and industrial water, particularly waste water. June 28.

XIX.—PAPER, PASTEBOARD, &c.

APPLICATIONS.

- 15,190. Brandenberger. Manufacture of cellulose films.* June 29.
 15,281. Brandenberger. Manufacture of cellulose films.* June 30.
 15,306. Lilienfeld. Process for coating or printing with viscose. June 30.
 15,555. Meister, Lucius, und Brüning. Manufacture of the paper machine of paper having relief-like effect [Addition to No. 10,529 of 1908. Ger. Appl., July 2 1908.]* July 3.
 15,855. Bloxam (Chem. Fabr. Griesheim-Elektron). Manufacture of celluloid-like products.* July 7.

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,994 (1908). Franz. Treatment of peat fibre and its manufacture into paper and cardboard. July 14.
 14,143 (1908). Lecoenr. *See under V.*

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

- 15,303. Cross. Manufacture of chloramine derivative. June 30.
 15,525. Wellcome and Barger. Manufacture of therapeutic compound. July 3.
 15,526. Wellcome and Barger. Manufacture of physiologically active base. July 3.
 15,552. Rose and Siddall. Rotary machine for extracting essential oils from limes, lemons, bergamots, & July 3.

COMPLETE SPECIFICATIONS ACCEPTED.

- 24,742 (1908). Gloystein. Manufacture of concentrated tobacco extract. July 14.
 27,038 (1908). Knoll und Co. Pharmaceutical preparations. July 14.

XXII.—EXPLOSIVES, MATCHES, &c.

APPLICATIONS.

- 15,363. Quick. Smokeless propellants for guns large calibre. July 1.

COMPLETE SPECIFICATION ACCEPTED.

- 12,506 (1909). Kilburn (Pieper). Explosives. July 1

Journal of the Society of Chemical Industry.

No. 15, Vol. XXVIII.

AUGUST 16, 1909.

No. 15, Vol. XXVIII.

Official Notice.

INTERNATIONAL EXHIBITION, BRUSSELS, 1910. CHEMICAL TRADES EXHIBIT.

The system devised for exhibiting chemical products at St. Louis in 1904, will be followed at Brussels: it enables every exhibitor to see in his own country, beforehand, how the goods will be shown; it supplies him with evidence that they are so shown; and will relieve him of all responsibility for their transport, installation, and presentation to the jury of awards. This will be the case for a comparatively small addition *pro rata* to the general charge for space (see this J., July 15, 1909, p. 684). The method of installation at St. Louis was as follows:—In each case a model was made of the showcase, with the ground plan of its shelves; and the specimens to be shown were arranged in this model showcase in London to the exhibitor's satisfaction. A photograph of the exhibit was taken; the specimens, the bottles they were to be shown in, and the ground plan were numbered correspondingly; and, the exhibit being then dismantled, could be set up again in the same way. At the Exhibition, there was a skilled man to receive the goods, to transfer them from the strong vessels in which they had travelled, and to install them in accordance with the numbered ground-plan. A photograph of the exhibit *in situ* was then taken. Showcases will shortly be on view at the Exhibitions Branch of the Board of Trade, Queen Anne's Chambers, Westminster, and the same system will be followed for the Chemical Section at Brussels. The section will be in charge of a competent technical assistant, able to explain the merits of the various exhibits.

London Section.

THE ACTION OF SULPHURIC AND NITRIC ACIDS IN THE NITRATION OF CELLULOSE.

BY C. NAPIER HAKE AND MARCUS BELL.

(See this J., May 15, 1909, pp. 457-464.)

Messrs. HAKE and BELL write as follows in reply to the points raised during the discussion:—"The term 'pioneering action,' used in reference to the function of sulphuric acid in nitration with mixed acids, implies that the formation of a compound of cellulose and sulphuric acid is a necessary stage in the normal process of nitration; that the whole of the cellulose nitrate produced must be freed by the replacement of sulphuric by nitric acid. The results given in our contribution are opposed to this view. In Table I., Section B, the results indicate that when a proportion of sulphuric acid in the mixture is high, a comparatively large proportion of sulphuric acid is combined, but that as the time of contact is extended, the nitrogen content of the product becomes higher, the sulphuric acid combined at the same time diminishing. It is this alteration in the product is due to replacement. It is how far to solution of the sulphuric acid compound, is not clear. By varying the method of preparation, products may be obtained which have the same composition as regards nitrogen and sulphuric acid combined (see Table V.), but our later work indicates that their properties do not carry this similarity further.

"The fundamental change which is readily brought about by the action of sulphuric acid on cellulose would suggest that a nitrate formed by substitution of nitric acid radicals on sulphuric would be a body totally distinct from a nitrate formed by direct nitration, and our experiments have confirmed this.

"So far, then, is a pioneering action of sulphuric acid from being a necessary factor in the production of cellulose nitrate, that any action of this nature tends to form a different compound, of inferior stability, and, moreover, lowers the yield obtained.

"In reply to Dr. Robertson's remarks as to the relative rates of esterification of nitric acid and sulphuric acids, we would point out that, as shown in Table I., a very small proportion of nitric acid in the nitrating mixture is sufficient to retard and largely to prevent esterification by sulphuric acid, so that even when the proportion of sulphuric acid is 10 parts to 1 part nitric (making the active mass of sulphuric acid relatively very high), the action of nitration still predominates."

DR. CHARLES F. MCKENNA IN THE CHAIR.

DETECTION OF METHYL ALCOHOL IN ETHYL ALCOHOL.

BY ANTON VORISEK, PHARM.D.

That the detection of methyl alcohol in the presence of ethyl alcohol is not a very simple matter, would appear from the number and variety of methods devised for that purpose. Even the methods now accepted as standard present some difficulties when the task is to detect small amounts, say two per cent. or less. When the quantity of the sample available happens to be limited the detection of small amounts is almost impossible.

Before the methods of purification of wood spirit were perfected, the detection of acetone, which always accompanied methyl alcohol, was practised and regarded as sufficient evidence of the presence of methyl alcohol. Other methods for the detection of methyl alcohol since devised may be, for convenience, divided into three groups.

1. *Physical methods.*—In a method originated by Duclaux, the surface tension of the liquid is measured, and from the value obtained, the calculation of the proportion of the two alcohols made. Leach and Lythgoe (1) employed an immersion refractometer, there being an observed difference of 83.4° between the two alcohols of 91 per cent. strength. A. Lam (2) bases his method on the difference in specific gravities of methyl and ethyl iodides. Separation of a compound of methyl alcohol with calcium chloride has also been practised.

2. *Esterification.*—The production of methyl salicylate, which has a characteristic odour, is well-known, but unsuitable for small amounts. Conversion into methyl oxalate and separation of this compound was devised by Hager. Here may be also included the method of Richter and Bardy (3), in which methyl iodide, dimethylaniline and methyl violet are successively formed.

3. *Oxidation methods.*—These are the more numerous. Commonly, the products of oxidation, giving characteristic reactions, are tested, though the amount of carbon dioxide produced has served to indicate the presence or absence of methyl alcohol.

As oxidising agents, the peroxides, permanganates, chlorates with hydrochloric acid, bichromate-sulphuric acid mixture, chlorine, bromine, hypochlorites, mercuric oxide, hot copper oxide, and others have been used. Out of these, the bichromate-sulphuric acid mixture, permanganate, and hot copper oxide (on copper spiral or gauze) are chiefly employed.

(a.) *Hot copper oxide* was first used for this purpose by Mulliken and Scudder (4) who state that 1 in 5 and even 10 parts of methyl in ethyl alcohol may be thus detected, but that methyl esters, if present, give a reaction for formaldehyde. They modified and improved their method (5) in respect to testing for formaldehyde with resorcinol. This method, modified by S. P. Sadtler (6) was adopted by the U.S. Pharmacopœia, VIII. D.R. Acetic aldehyde is boiled off and the liquid tested for formaldehyde with a weak solution of resorcinol and strong sulphuric acid. Upwards of 2 per cent. may be detected. The observations of others that ethyl alcohol will, by oxidation with hot copper wire, yield some formaldehyde, especially when volatile impurities are present, have been confirmed in experiments with this method. After oxidation with hot copper oxide A. B. Prescott (7) destroyed the acetic aldehyde with hydrogen peroxide, and tested for formaldehyde with an alkaline solution of phloroglucin, as devised by Vanino (8). In the copper spiral method of L. D. Haigh (9), the liquid after oxidation is filtered, acetic aldehyde removed by boiling, and test made with phloroglucinol in a white porcelain dish. The same colour was produced even with pure ethyl alcohol.

The copper spiral method was criticised by E. Jandrier (10), who found that acrolein reacts with resorcinol like formaldehyde, and that traces of furfural will effectively cover relatively large amounts of formaldehyde. Scudder and Riggs (11) showed that many organic compounds give formaldehyde on oxidation with copper spiral, pronouncing the method unreliable.

(b.) *The potassium permanganate* method of P. Cazeneuve was modified by Habermann and Oesterreicher (12), the oxidation with $N/10$ permanganate being carried out in an alkaline solution. Limit, 5 per cent. Sanglé-Ferrière and Cuniasse (13) oxidised in sulphuric acid solution with a saturated solution of permanganate, neutralised the liquid and tested with phloroglucinol. Fendler and Mannich (14) selected and elaborated the permanganate method. They oxidise in sulphuric acid solution, in the cold, with the powdered salt, and test with morphine-sulphuric acid. The method did not give satisfaction with distillates from spirits, tinctures, or other aromatic preparations.

(c.) *The oxidation with the bichromate-sulphuric acid mixture* originated with J. F. Miller (15). Depending on the concentration of the reagents, temperature, and the duration of treatment, methyl alcohol will be converted into methylal, formaldehyde, or, according to Thorpe and Holmes (16), completely into carbon dioxide and water. A. Trillat (17) says that 0.5 per cent. of methyl alcohol may be detected in absolute alcohol by his rather elaborate method, in which five-hour digestion, two distillations, removal of diphenylamine with steam, and a treatment with suspended lead peroxide in acetic acid solution must be made. He modified his method for the treatment of spirits and the method was further modified by J. Wolff (18). The time of digestion was then shortened to 1 hour in the method of E. Voisenet (19), in which the two final fifths of the slowly distilled liquid are tested with albumin, hydrochloric acid, and nitrous acid. Other aldehydes react, but their colour is readily discharged by traces of hydrogen sulphide or sulphur dioxide. L. E. Hinkel (20) called attention to a rather peculiar phenomenon, namely, that if the bichromate mixture be dilute and heat applied, the amount of formaldehyde formed is exceedingly small. He adds that less than 5 per cent. of methyl alcohol cannot be detected with certainty. In his method the last three-fifths of the distillate are tested with a solution of morphine hydrochloride and strong sulphuric acid.

It was while trying the three most commonly used oxidising agents that difficulties were encountered. A reaction for formaldehyde was often obtained with ethyl alcohol alone or with distillates containing no methyl alcohol. It was not possible to detect small amounts with certainty. The "bichromate" methods were found to be the most reliable, under certain conditions, though, at best, they are neither simple nor rapid.

Since the bichromate-sulphuric acid mixture will not only produce methylal and formaldehyde, but will oxidise methyl alcohol completely (16) to carbon dioxide and water, the

use of a weak solution of chromic acid suggested itself. Trials were made with its solutions of varying concentration and without the customary sulphuric acid. The results were encouraging. Digestion at 60° C. was at first practised, but was later found unnecessary.

The method.—In the method finally devised, oxidation is made with a weak solution of chromic acid, free from sulphuric acid. The acid is mixed with a small volume of the sample and the liquid at once distilled. The distillate is tested for formaldehyde.

An air condenser. The nearly horizontal sections are 16 ins. to 18 ins. long; the middle, 14 ins.; tubing, 2 in.

It was thought that an air condenser which could be readily detached for cleaning could be employed. The kind, represented in the figure, has served this purpose admirably. In distillation it is held in position by means of a wooden test tube holder secured in a small metal clamp.

Of the numerous tests for formaldehyde, the modified Helmer's test was selected, and when used as here directed gave complete satisfaction. Liquids containing other substances should, of course, be distilled direct or after dilution with water. By using another air condenser this distillation is performed with expedition, only 5 to 15 drops of the distillate being required.

Reagents needed.—*Chromic acid solution*, in distilled water, containing 0.8 per cent. of CrO_3 , free from sulphuric acid. *Albumin solution*.—The white of one fresh egg is mixed with 50 c.c. of distilled water, filtered, and preserved with a few drops of chloroform. Less sensitive on long keeping. *Aldehyde-free milk* answers nearly as well. *Ferric chloride solution*, containing 0.4 per cent. of ferric chloride corresponding to 0.25 per cent. of iron. *Sulphuric acid*, pure, concentrated, and specially free from nitric and nitrous acids. *Pumice*, in small pieces.

Procedure.—0.5 to 1.0 c.c. of the sample of alcohol or of an alcoholic distillate is placed in a 6 inch test tube 1 c.c. of the chromic acid solution added, and the liquid diluted with water to 4 to 5 c.c. Two or three small pieces of the pumice are dropped in, the test tube connected with the condenser (see figure) and the liquid distilled into another test tube by boiling briskly over small flame. When 3 to 4 c.c. of the liquid have passed over or when only about 0.5 c.c. remains behind in the first test tube, the condenser is detached and rinsed with about 2 c.c. of distilled water, into the receiving test tube. To the distillate are added: 1 drop of ferric chloride solution, 2 drops of albumin solution, and after mixing, 4 to 5 c.c. of the pure sulphuric acid are poured in, slowly and carefully as a layer, generation of much heat being avoided. The zone of contact is then observed without disturbing the liquids, against a white background. A sharply defined, violet zone appears almost

once if the proportion of methyl alcohol is above 5 per cent. With smaller amounts but more than 1 per cent., colour shows within one minute; several minutes will be required for the colour to appear with less than 1 per cent. of methyl alcohol. Pure ethyl alcohol, treated in this manner, gives no colour. When organic impurities (other than methyl alcohol) are present which cannot be removed, a yellow to reddish colour is often obtained, but not violet. The violet colour is intensified on standing, warning, so that the entire liquid becomes coloured violet to lavender if the test tube be placed in boiling water for some time. Dilution with water will diminish the intensity of the colour, which is not affected by cerin or 50 per cent. sulphuric acid.

Albumin in strong solutions gives with concentrated sulphuric acid a variety of colour reactions. It must be used in excess, and only traces of ferric chloride could be added to obtain perfect blank tests. Various ferric salts have been recommended, but trials have shown the chloride to be the best suited. This is in agreement with the conclusions of Shrewsbury (21). 5 to 5 drops will be found a sufficient quantity of milk for the test. Commercial sulphuric acid, as used bychner (22) was found unsuitable; the acid which appeared to be tried gave no reaction with a weak maldehyde solution, with which a pure acid reacted. Investigation showed that traces of nitric or nitrous acid will affect the reaction to a marked degree and that in larger amounts the acids will prevent the reaction entirely. The other impurities of commercial sulphuric acid, arsenic, selenium, lead, and sulphur dioxide showed marked influence on the reaction.

Under the conditions here described, it was possible to detect as little as 0.001 gm. of methyl alcohol in 1 c.c. of the ethyl compound. Experiments were made with alcoholic solutions of chloroform, chloral hydrate, acetone, sulphur, phenol, resorcinol, methyl salicylate; tinctures of camellia, ginger, benzoin; soap and chloroform liniments, with negative results. A good reaction was obtained in each case when 1 drop of a 10 per cent. alcoholic solution of methyl alcohol was added. A notably different behaviour was observed with benzaldehyde, which, when treated, gave a green-blue zone; on warming, the entire liquid acquired an indigo-blue colour.

Conclusion.—If the described method has any merit and advantages they would seem to consist of the following:—

1. The use of a small quantity of the sample (0.1 c.c. of 1 per cent. methyl alcohol gave a good reaction), other than requiring 10 to 50 c.c.
2. Simplicity and ease of execution. No special apparatus is required.
3. Rapidity; 10 to 15 min. in all being consumed. Much time is thus saved when a number of tests is made.
4. Detection of small quantities, 0.001 gm., and even less.

It is hoped that the method will be found useful and that it may be modified to become of value for quantitative determination of methyl alcohol.

THE CHEMICAL SCHEDULE AND THE TARIFF.

BY R. W. MOORE.

Owing to the somewhat superficial comments often appearing in public print regarding the manner in which tariffs are framed, the idea prevails in some quarters that the tariff law is the result of incomplete consideration of the needs of the country and scanty information regarding the merchandise on which duty is levied or which is free of duty. Nothing could be further from the truth; and it is only just to our representatives in Congress and in the Senate to point not only to the immense volume of facts which they have at their command, but the masterly manner in which conflicting statements are weighed and sound and logical conclusions arrived at.

The present revision of the Dingley tariff was undertaken by the Ways and Means Committee of the House early in the summer of 1908. Under the supervision of the Clerk, Mr. Wm. K. Payne, a most thorough and painstaking quarto volume of nearly 1000 pages was prepared, with the modest title "Notes on Tariff Revision," in which each paragraph of the tariff of 1897 was separately considered, and in a parallel column such changes in the wording of the law were given in italics as were deemed necessary for its proper enforcement. No rates of duty were given, this being very properly left for Congress to determine. A skeleton tariff was then prepared, in which the weak points of the present law were noted and suggestions made to remedy the defects. In addition to this, under each paragraph a brief description of the goods was given with statements showing the amount imported per annum, the amount of duty paid, and decisions and interpretations given to the particular paragraph of the law by the Board of General Appraisers and the United States courts. To prepare this volume almost every department of the Government was consulted, while in the chemical schedule use was made of such authorities as the U.S. Dispensatory and Pharmacopœia, Watts, Allen, Thorpe, Lange, Redwood, Rensen, and many others. The amount of information thus obtained was certainly great, and derived an added value from its orderly arrangement and availability.

With this work as a basis, the Committee on Ways and Means held extended hearings on the chemical schedule and reviewed numerous briefs, most of which were published in a large volume. Anyone who has attempted to digest this book will at once see the great labour involved in reconciling the statements of so many conflicting interests, but it must be remembered that the members of the Committee are active and practical men of affairs and capable of weighing evidence. As to how many times the chemical schedule of the tariff bill was taken up and considered only the members of the Committee know. In my official capacity, I was present at three separate considerations by the Ways and Means Committee of the chemical schedule, where each item was minutely explained, the volume of imports under the present law noted, and statements regarding the effect of raising or lowering the rates of the Dingley law discussed. There was no haste, but the greatest deliberation, and when facts were wanting, time was taken to secure them. The discussions were pointed, intelligent, and indicated, especially on the part of the Chairman of the Committee, an astonishing grasp of the infinite detail of a tariff bill.

When the Committee on Ways and Means reported to the House, their work came under fire, as was to be expected. Many amendments were adopted, but in the main the chemical schedule remained as reported. Little or no change was here made in the wording, which had been particularly considered by the Committee with the view of making each paragraph clear and distinct in meaning. It is not too much to say that the chemical schedule in this respect compares very favourably with the other schedules. Loose designations and descriptions have been avoided and clear and definite terms employed. Assistance to attain this end was given by both chemists and lawyers. It is not realised as fully as it should be that the definite quality of a tariff schedule is of immense importance, both to the importer paying duty and to the manufacturer seeking protection. An indefinite low rate plus a lawsuit will often make the goods cost more to land

than a higher definite rate, while a loosely drawn provision will allow the admission at a low rate of goods similar in character to others bearing a higher rate. Thus zinc in pigs, under the Dingley tariff, pays 1½ c. per lb., but zinc dust is allowed to enter free of duty as a crude substance used in dyeing. Oxide of cobalt pays 25 c. per lb. duty, but a cobalt ceramic colour, worth about the same price, it containing lead, is entered at but 5 c. per lb. duty, under a too general paragraph designed to cover lead vermilions. The latter case is still, however, before the United States courts, and may result in establishing the higher and more uniform rate.

The treatment of the chemical schedule in the Senate was naturally very similar to that of the House, though even more attention was given to the administrative feature of the bill. Particular inquiry was directed to the exact meaning of the chemical terms used. Public hearings were not held by the Senate Finance Committee, chiefly on account of the amount of time consumed by those representing various interests when addressing the Committee, but various representative men were consulted, among them several members of the Board of General Appraisers for the administrative features, Treasury officials, and many examiners from the New York Appraisers' Office, who are personally familiar with the great variety of goods imported at this port. Further, several representative chemical manufacturers had an opportunity to be heard, and a large number of written statements from chemical manufacturers and importers were received and considered. Practically a new bill was drawn by the Senate Finance Committee, using the House bill as a basis, as the House Bill had used the Dingley Tariff Act. On its presentation to the Senate it was subjected to severe attack, though little of this was specially directed against the chemical schedule. It was claimed by its opponents that the bill contained many "jokers" or obscure provisions by which rates were raised though apparently lowered. No "jokers" were found in the chemical schedule, which passed through the contest in practically the form reported by the Committee.

An ideal tariff from an administrative standpoint is one that is framed in such a manner as to be clear and easy of interpretation. Litigation is expensive and interferes with commerce. A clear and definite rate is satisfactory to all. A careful perusal of both the House and Senate bills will show that much has been accomplished in this direction. The searching criticism of the Senate bill, which is now under way, will doubtless result in further improvement of the measure, and it is well that it should be searching, for whatever weak points are discovered and remedied will add to the real strength of the law when further tested in the courts.

The rates of duty of the House and Senate bills are still under consideration, and any attempt to consider their bearings on chemical industry would have but a temporary value. In general there was a substantial reduction in the House bill and a tendency towards partially restoring the Dingley rates in the Senate bill. The final results promise to be close to a middle course with a leaning towards the lower rates. The enormous difficulty of enacting a tariff bill must be noted. When it is considered that everything that is capable of importation must be provided for, and in such a manner as to bear a proper relation to everything else, that arguments *pro* and *con* are submitted in countless number, and that the revenue-producing feature must be kept continually in mind, the magnitude of the task can be seen. Courts listen to arguments respecting one kind of merchandise at a time, but the Committees of Congress consider whole schedules of the tariff in a day. The statements of attorneys must be presented to the court in proper form; the Committee hear and read statements of all kinds and practically at all times. To bring an orderly law from this chaos requires great clearness of mind and grasp of detail. Not even a perfect law would escape violent criticism, and satisfactory though it might be in principle, it would be years before its character could be fully appreciated. It is highly probable that the manner of framing the tariff law, though subject to the most hostile criticism, is as good as is provided for under our laws, and that the compromises which are so unfavourably regarded have as

much wisdom in them as many of the court decisions which are received with universal respect. A body of lawyers would probably draw a bill that no body of officials could administer without calling in one or more lawyers at every step and causing a vast amount of uncertainty and litigation. A body of Government officials would probably draw a bill that would win every case that the Government had ever lost. A body of specialists would draw a law in which the lawyers would find more loopholes than law. A body of manufacturers would probably draw a bill that would finish for all time the ultimate consume while the bill drawn by a body of chemists and exper would probably not be written in the English language and would be somewhat greater in volume than Webster Unabridged Dictionary; but mix all the foregoing together and something of value would result. Repeat this process several times and a workable tariff would be obtained but at an expenditure of time which would be beyond forecast.

The often suggested remedy, that of a tariff commission may or may not be the solution. The success of commissions is not on the whole flattering. Any tariff bill must represent a consensus of opinion, the wider the better. A commission can hardly do this. It is prone to proceed in its own way, which may be laborious and scientific and yet fail of its end. The complex nature of the problem is the chief difficulty. The lawyer, expert, Customs official, chemist, and economist should all be felt in the tariff. Information is not lacking. The Government possesses to-day in the Treasury, State, Agriculture and Commerce and Labour Departments a colossal mass of facts on almost every item of the tariff. What is needed in my opinion, is the proper and orderly arrangement of these facts by a body of men whose conclusions would amount to demonstrations in order that Congress, when exercising its legal functions in enacting a tariff, should be able to obtain the whole truth on each and every item.

UTILISATION OF MAGNESIA IN THE PREPARATION OF OILS IN POWDER FORM.

BY OTTO B. MAY.

In magnesia has been found a substance with which castor oil may be mixed, without in the least affecting its properties. The castor oil magnesia powder contains 50 per cent. of the oil, and is stable, tasteless, odourless, readily taken, and well borne. Its therapeutical efficacy is as great as the same dose of pure castor oil, and the magnesia contributes its own properties to the powder.

The use of magnesia as an excipient to convert liquid into dry or semi-dry substances is not new. The U.S. Pharmacopoeia of 1890 contains a preparation—the *massa copaiba*—which was prepared by heating magnesia water, and copaiba balsam until a plastic mass was obtained. On using more magnesia than the formula asks for a copaiba powder would result. It is further more known that with glycerin, sugar, and stearol magnesia forms solid masses, which can be reduced to powder. In all these cases, however, the magnesia combines chemically with the substances with which it is mixed. In the castor oil powder the oil is in no way changed, that is to say, castor oil powder is not magnesia soap of castor oil. No glycerin or free fatty acids (except those present in the original oil) can be found, as would be the case if saponification had taken place. On extracting the castor oil powder with ether in the Soxhlet apparatus from 96 to 98 per cent. of the entire fat content may be recovered. The fact that not all of the oil is thus extracted at first gave rise to the thought that at least a part of the oil was saponified. To settle this question the powder was rubbed up with water and enough hydrochloric acid added to decompose the magnesia. The resultant liquid was then shaken out with ether. In this way all the oil incorporated was recovered. The examination of the oil extracted in the Soxhlet apparatus or extracted after decomposition of the powder with acid differed only in the one point, that the acid value of the former was zero; all other constants were the same as those of the

ginal oil. On mixing the castor oil with magnesia, the free fatty acids present in the oil are neutralised, forming minute quantities of magnesia soap, which acts as a kind of catalytic agent, emulsifying the balance of the oil and distributing it very thoroughly. On drying the paste formed by mixing castor oil, magnesia, and water, the oil globules do not unite again, but remain the state of the original fine subdivision. On examining the powder under the microscope with a magnification of 450, very few fat globules can be observed, almost the entire amount of oil having been absorbed so firmly that no oil separates out when the powder is mixed with hot or cold water and allowed to stand.

Mr. D. T. ATKINS (of Messrs. Eimer and Amend), described the working of the new Emerson bomb calorimeter, giving figures showing its efficiency as compared with the standard Mahler bomb calorimeter. He also explained the working of the Barnes telephone pyrometer, with the galvanometer and telephone receiver, indicating its advantages over some similar pyrometers. The Wanner pyrometer was also shown. A further exhibit consisted of a collection of fused silica ware, including dishes, muffles, tubing, and other laboratory appliances, and also a variety of fused alumina ware, such as muffles, crucibles, combustion bulbs, tiles, bings, &c., which are recommended for metallurgical and other high temperature experiments. Other exhibits were a Williams modified Westphal specific gravity balance for liquids and solids, and a new graphite rotating cathode for the rapid electrolytic termination of metals.

PROFESSOR SCHOFIELD IN THE CHAIR.

A RAPID AND ACCURATE METHOD OF ESTIMATING IRON IN IRON ORES.

BY J. S. MACLAURIN, D.S.C., AND W. DONOVAN, M.S.C.

Anyone who has had experience in the estimation of iron in magnetites and hematites must have frequently experienced difficulty in getting the iron into solution within a reasonable time. Such difficulties led one of us to subject the ore to a preliminary heating in hydrogen gas. The iron could then be readily dissolved in hydrochloric acid, reduced by stannous chloride, and estimated volumetrically. In these estimations, however, potassium permanganate could not be used if really accurate results were required, owing to the disturbing effect of hydrochloric acid, and consequently it was necessary to employ the bichromate method, which has the serious defect of requiring an external indicator. These defects have been entirely removed by modifying the process, which is now carried out in the following manner.

A weighed quantity of finely ground ore is introduced into a hard glass bulb tube by means of a small copper spoon (made of thick copper foil bent into the desired shape and soldered to a stout piece of copper wire). The bulbs, carrying narrow glass tubes, are then fitted into the ends of the tube. Should the ore contain organic matter, air is drawn through the tube by means of a rubber pump or aspirator, and the bulb heated to redness for a few minutes, being gently rotated backwards and forwards during the heating. It is then allowed to cool, the air current stopped, and a stream of hydrogen or carbon gas substituted. This is lighted at the exit end of the small glass tube. Should hydrogen be used, the bulb may be prevented from closing up by the use of a platinum tip, made by rolling a small strip of platinum round the end of the tube. After heating for from 15 to 30 minutes, according to the nature of the ore; the

tube is allowed to cool, the stream of hydrogen or carbon gas shut off, and the reduced ore shaken into a flask containing one or two grams of sodium bicarbonate and a little water. Any ore remaining in the tube is washed into the flask with dilute sulphuric acid. By this means sufficient carbon dioxide is evolved to fill the flask, and so prevent oxidation of the iron. In order to still further guard against oxidation, the flask is closed by a rubber cork carrying a short exit tube and an inlet tube which dips beneath the surface of the solution in the flask, through which a steady stream of carbon dioxide is allowed to flow from a Kipp apparatus. The flask is then heated, and the solution boiled for from 5 to 20 minutes, according to the ease with which the iron dissolves. This operation requires little or no attention, and can be carried out while another sample is being heated in the bulb tube. When all the iron is dissolved, the solution is allowed to cool in the air, or more rapidly by closing the exit tube with the finger and allowing water to flow over the outside of the flask, the carbon dioxide apparatus being still, of course, attached. It only remains to shut off the carbon dioxide, remove the cork from the flask, wash the tubes with a little water, and titrate the solution with potassium permanganate.

This process gives very constant results, duplicate determinations agreeing excellently. Thus, in estimating the iron in 55 samples of limonite, the greatest difference in the duplicate determinations, which were made quite independently of one another, was 0.22 per cent. of iron, and the average difference only 0.09 per cent. In many of these determinations, after titrating with permanganate, the solution was reduced with sulphuretted hydrogen, the excess of this gas being removed by passing carbon dioxide through the boiling solution (Hillebrand's method). The iron so reduced was then estimated by titration with permanganate, and in every case the result so found agreed closely with that previously found by our method. This agreement shows that the whole of the iron dissolved out of the reduced ore goes into solution as a ferrous salt, and is therefore estimated in the subsequent titration. Moreover, the residues contained no iron. This was proved by fusing with sodium and potassium carbonates, and testing for iron.

We had thus conclusive proof of the accuracy of our results, but for the sake of comparison with other methods, the following determinations on five limonites were made. The results given under A are by our method. Those under B were determined by dissolving in hydrochloric acid and stannous chloride, adding mercuric chloride to remove the excess of stannous chloride, phosphoric acid and manganese sulphate to improve the conditions for titration, and finally titrating with permanganate. In column C of the table, the results were obtained by dissolving in hydrochloric acid, reducing with lead and copper sulphate, and titrating with potassium bichromate.

The results are percentages of iron.

A.	B.	Difference from A.	C.	Difference from A.
44.03	43.13	-0.90	43.42	-0.61
49.21	49.06	-0.15	49.29	+0.08
36.57	36.99	+0.42	36.66	+0.09
26.73	26.46	-0.27	26.78	+0.05
35.52	35.97	+0.45	36.02	+0.50

Mean diff. from A. -0.09 Mean diff. from A. +0.02

The titration in the case of B is not nearly so satisfactory as in A, owing to the presence of a large amount of precipitate, which somewhat masks the ending. Duplicates by this method differ to a much greater extent than do those by the A method. In making determinations by method C the solution of the ore is very slow—sometimes taking hours to accomplish, and, owing to the necessity for an external indicator, the titration is not nearly so simple and satisfactory as in the A method.

Our method is thus shown to be well adapted for the estimation of iron in limonites. It may also be used with advantage for the much less soluble magnetites, ilmenites, hematites, &c. In this case the ore requires fine grinding

and half an hour's reduction in hydrogen; coal gas cannot be used, as it does not give complete reduction. If the hydrogen be made from commercial zinc, it should be purified from antimony and arsenic, which interfere with the subsequent titration. The purification is most simply effected by passing through a hard glass tube wrapped in thin sheet asbestos, and heated to redness by a long flat burner. The tube should be from 15–18 ins. long, and about $\frac{1}{2}$ in. in diameter, reduced to $\frac{1}{4}$ in. or less for 4 or 5 ins., to allow of the ready deposition of antimony and arsenic. It is interposed between the source of hydrogen and the hard glass bulb tube in which reduction of the ore takes place. This treatment removes all but minute traces of arsenic and antimony, and these may be got rid of by passing the hydrogen through one or two wash bottles containing glass wool saturated with chromic acid.

Using this method we got the results given in column A of the following table. Those shown under B were obtained from the same solution in the following manner. After titrating with permanganate (for A determinations) the solutions were reduced by hydrogen sulphide (Hillebrand's method), the excess removed by carbon dioxide, and again titrated with permanganate. The results so obtained are shown in column B. As a further check on these figures, the ore was fused with sodium and potassium carbonates, dissolved in sulphuric acid, reduced by means of sulphuretted hydrogen, &c., as before, and titrated with potassium permanganate, the percentages of iron so found being shown in column C. Or it was fused as before, dissolved in hydrochloric acid reduced by stannous chloride, and titrated with bichromate, the results being shown in column D.

	A.	B.	C.	D.
Magnetite, Taranaki, N.Z.	59.62	59.90	60.02	59.75
" " "	57.75	—	57.72	—
" " Quebec, Canada	64.34	—	—	64.12
" " France, . . .	67.17	67.24	—	67.34
Ilmenite, Norway . . .	43.48	—	43.53	—
Micaceous iron ore	57.39	—	—	57.50
Hematite, Ohio, U.S.A.	61.18	61.24	—	—

These figures are sufficient to show that our method gives very satisfactory results for such refractory ores as magnetites and ilmenites. For these ores it has the further merit of making the estimation of titanium quite a simple matter. This is done by adding hydrogen peroxide to the solution after the permanganate titration, and estimating the percentage of titanium by comparison with a standard solution of that substance. By this means, 9.12 per cent. of titanium dioxide was found in the Taranaki magnetite, as against 9.27 per cent. obtained by fusion. Moreover, it was found that none of the insoluble residues contained more than minute traces of titanium.

To recapitulate very briefly, the process consists of the following steps:—(1.) Roasting the finely ground ore. (2.) Reduction of the roasted ore by heating in coal-gas or hydrogen. (3.) Solution of the reduced ore in dilute sulphuric acid in an atmosphere of carbon dioxide. (4.) Titration of the resulting solution by potassium permanganate. The advantages of the process over those commonly employed are the removal of any organic matter which might interfere with the subsequent titration, the ease and completeness with which the ores are dissolved, the accuracy of the titrations, and the possibility of estimating titanium in the same solution.

NOTE.—Since writing this paper our attention has been drawn to the fact that a somewhat similar method is described in Crookes's Select Methods in Chemical Analysis, 3rd Edition. That method we find involves the use of a porcelain tube and platinum boats. It requires from four to six hours for four determinations, and it admittedly fails to extract the whole of the iron when dealing with magnetites, this being due no doubt to incomplete reduction.

In our method, on the other hand, much simpler apparatus is used, complete reduction is easily and quickly obtained in the rotating bulb tube, the whole of the iron goes into solution, and the determination is made accurate and reliable by purifying the hydrogen. This was found to be a very important step in the process, because when using unpurified hydrogen, results differing from the true value by several per cent. were sometimes obtained.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Treating materials with air or other gases or vapours for drying, bleaching and other purposes. Toulinson-Haas, Ltd., Manchester. From F. Haas, Ges.m.b.H., Lennep, Germany. Eng. Pat. 14,914, July 2, 1908.

THE claim is for improvements in the apparatus described in Eng. Pat. 15,108 of 1903 and consists in providing valves by means of which any one or more of a series of drying chambers can be cut out of the drying system, and atmospheric air, which may be first moistened if desired, can then be drawn through the chambers so cut out of the series. Further, a portion of the air drawn through the apparatus may be circulated through certain of the chambers to admit of its being used continuously.

—W. H. C.

Packing pieces for chemical absorption, condensing and like towers. E. P. Peyton, Birmingham. Eng. Pat. 18,831, Sept. 8, 1908.

FIG. 1.

FIG. 2.

THE packing pieces have the form shown in plan in Fig. 1, and in cross-section in Fig. 2. They consist of a circular or polygonal central portion, *a*, having curved surfaces provided both above and below with projecting radial ribs or bearers, *b*.—W. H. C.

Apparatus and tools; Manufacture of —. Siemens und Halske A.-G., Berlin. Eng. Pat. 19,564, Sept. 17, 1908. Under Int. Conv., Sept. 26, 1907.

THE alloys of tungsten and nickel, containing more than 60 per cent. of tungsten and more than 1 per cent. of nickel (see Fr. Pat. 393,595 of 1908; this J., 1909, 149), are employed for making apparatus, tools, &c., which are exposed to chemical attack.—T. F. B.

Fire extinguishing compounds. E. M. Davidson, New York. Eng. Pat. 3704, Feb. 15, 1909.

THE claim is for a fire-extinguishing compound consisting of a solution of hydrochloric acid, sulphur dioxide and carbon dioxide in carbon tetrachloride.—W. H. C.

Centrifugal separator. T. S. Patterson, Rosemont, Pa., Assignor to The Oil and Waste Saving Machine Co., Philadelphia, Pa. U.S. Pat. 926,596, June 29, 1909.

THE claim is for a perforated cage or frame which fits into the drum or bowl of the machine and can be withdrawn and opened out for the purpose of removing the materials treated.—W. H. C.

Separation of gases by absorption by a circulating liquid; Apparatus for the —. M. Honigmann, Ger. Pat. 211,065, Nov. 29, 1907.

THE apparatus is shown in the figure. The absorbing liquid flows down the pipe, *a*, sucking in the gas through the rose, *b*, and then flows in succession, with the entrained gas, through the receptacle, *c*, the pipe, *i*, the receptacle, *e*, the pipes, *g* and *f*, and the receptacle *h*. The unabsorbed gas flows upwards through the screen, *d*, and the pipe, *f*, and assists the circulation of the liquid; it may be withdrawn from the receptacle, *h*. The absorbed gas passes with the liquid into the receptacle, *e*, to which may be connected any suitable means for removing it.—A. S.

II.—FUEL, GAS, AND LIGHT.

Vertical retorts; The Glover and West — at St. Helens. H. G. Colman. J. Gas Lighting, 1909, 106, 632-637; 107, 166.

THE retorts are 20 ft. high and oval in cross-section, 24 ins. by 12 ins. at the top increasing to 30 ins. by 16 ins. at the bottom. Each retort is capable of carbonising

2½ tons of coal per 24 hours and they are worked continuously, the coal being fed into the upper end by gravity from a charging hopper which is refilled at intervals, and the coke being continuously removed from a horizontal plate, which is fixed just below the lower opening, by a rotating blade or "wiper" into a receiving hopper from which the coke is withdrawn at intervals. The retorts are set in a furnace and heated by gas from an external producer. In order to obtain regular and uniform heating, the furnace is divided into a number of sections by horizontal partitions, the supply of air and gas to each section being controlled separately. The lower 3 feet of the retort are not heated but serve as a cooling chamber for the coke, the secondary air being conducted through flues arranged around this portion so that it becomes heated. Very little heat remains in the coke when discharged, so that only a small amount of water is required for quenching. The gas leaves the retort by a horizontal pipe situated near the top. The results of two trial runs with different qualities of coal, carried out under the supervision of the author, are given below in tabular form.

	I.	II.
Kind of coal	Orrell nts.	Thornley coal.
Locality	Lancashire.	Durham.
Percentage of ash in coal	6.94	3.24
Percentage of moisture in coal	3.95	1.08
Yield of gas in cub. ft. per ton ..	11,448	13,102
Average illuminating power, in candles	16.28	15.56
Calorific power in B.Th.U. gross ..	588.8	573.6
Do. do. net	529.6	514.5
Average composition of the gas—		
Carbon dioxide	1.97	1.00
Unsaturated hydrocarbons ..	2.70	2.85
Oxygen	nil	0.05
Carbon monoxide	9.90	8.70
Methane	31.97	29.05
Hydrogen	50.67	54.70
Nitrogen	2.73	3.20
Yield of coke in cwts. per ton, moist ..	14.8	15.6
Do. do. dry	14.2	14.2
Percentage of ash in coke	10.8	4.8
Do. moisture do.	4.0	9.5
Fuel used in gas generator, as percentage of dry coke	12.06	12.3
Yield of tar in gallons per ton ..	17.2	12.3
Sp. gr. of tar	1.076	1.119
Quality of tar	thin	rather thicker
Water in tar, per cent.	5.0	—
Composition of tar freed from liquor—		
Percentage by weight of light oils distilling up to 170° C.	3.0	3.7
Percentage of middle oils distilling from 170°–270° C.	27.0	20.2
Percentage of heavy oils distilling from 270°–350° C.	23.8	23.1
Percentage of pitch remaining at 350° C.	15.9	52.6
Percentage of naphthalene	4.5	4.8
Percentage of free carbon	2.5	4.2
Yield of ammonia equal to lb. ammonium sulphate per ton ..	33.4	26.7
Yield of cyanogen as Na ₄ Fe(CN) ₆ ·10H ₂ O, lb. per ton ..	5.5	5.3
Total sulphur in gas after purification with oxide only, grains per 100 cub. ft.	37.5	20.8
Naphthalene in purified gas, grains per 100 cub. ft.	—	2.7

The advantages of the vertical retort are summed up as follows:—increased yield of gas, tar and ammonia per ton of coal carbonised; coke of better quality obtained; no trouble with stopped ascension pipes; increased yield of gas per retort and on same ground space; improved labour conditions and considerably reduced cost of labour; great economy and saving in first cost of land and buildings, and lastly, reduced wear and tear in retorts.—W. H. C.

Carbon bisulphide; Removal of — [from coal gas]. J. Matwin. J. für Gasbeleucht., 1909, 52, 602–604.

GAS free from sulphuretted hydrogen and containing 98 to 122 grms. of sulphur per 100 cub. m. was passed through wood charcoal in a tube 80 cm. long and 13 cm. in diameter. The quantity of sulphur in 10 cub. m. of the gas was reduced by passing it through 1 kilo. of

charcoal, to 29.2 grms. per 100 cub. m. The calorific value of the gas was not affected, but the candle-power was reduced from 13 to 12 Hefner units. The charcoal can be regenerated by soaking it in water and afterwards drying it at 50° C. The action of various solvents on the crude gas was as follows:—

Solvent.	Quantity of sulphur in 100 cub. m. of the washed gas.
	grms.
Anthracene oil mixed with 10 per cent. of fish oil	58.8
Anthracene oil mixed with 10 per cent. of turpentine oil	61
Anthracene oil mixed with 10 per cent. of amyl alcohol	59
Anthracene oil mixed with 10 per cent. of acetone	53.6
5 grms. of colophony dissolved in 15 grms. of linseed oil and mixed with 80 grms. of anthracene oil	60.0
Colophony dissolved in alcohol and mixed with anthracene oil	53.8
Concentrated solution of colophony in benzene and anthracene oil	56.6
10 grms. of colophony dissolved in 90 grms. of anthracene oil	64.3
Colophony dissolved in 4 parts of linseed oil	26.5
Rape oil	34.1

Linseed oil and rape oil absorb the heavy hydrocarbons as well as the carbon bisulphide.—A. T. L.

PATENTS.

Anthracite dust; Agglomeration of — by the products of distillation of coal. J. Dybowski. Fr. Pat. 398,232, Dec. 31, 1908.

ANTHRACITE dust is ground and mixed with tar, and the mass is heated in a retort until the retort is brought to a red heat and no more gases are evolved. After cooling, the product is broken into pieces of convenient size.

—A. T. L.

Coke-oven. W. M. Person, Sparrows Point, Md. U.S. Pat. 926,285, June 29, 1909.

THE vertical heating flues, 11, are divided into groups by the vertical walls, 14; opposite pairs of groups are connected by horizontal flues, 15; and each group has a separate combustion chamber, 12, to which gas is supplied by the pipes, 17.—W. H. C.

Creosote or similar substance; Use of — for internal-combustion engines. C. Rodriguez. Fr. Pat. 397,847, Dec. 24, 1908.

THE patent is for the use of crude creosote or similar substances in engines of the Diesel type, in place of petroleum where this is difficult to obtain.—A. T. L.

Fuel for use in place of petrol for motor-car and similar engines. G. Thuillier. Fr. Pat. 398,239, Mar. 18, 1908.

THE patent is for the use of wood-charcoal in a suitable gas-producer so as to obtain a continuous supply of clean producer gas. The apparatus required is light, since a shallow fuel bed is sufficient and no purifying apparatus is necessary.—A. T. L.

Producer gas; Process for enriching — in carbon monoxide by introducing carbon dioxide into the producer. H. Trachsler and F. Ernst. Ger. Pat. 211,575, May 15, 1908.

LIMESTONE or other carbonate is mixed with the fuel supplied to the producer.—A. S.

Tar; Process for the separation of — from gases obtained from combustible materials. C. Otto und Co., Ges.m.b.H. Ger. Pat. 211,577, Oct. 8, 1908.

IN the production of gas from combustible materials, such as coal, the portion of gas obtained in the last stage of the operation is almost or entirely free from tar. According to the present patent, this portion of the gas is led off separately from the major portion evolved earlier, which latter is freed from tar by one of the known methods, and then mixed with the smaller portion of the gas collected separately.—A. S.

Carbon bisulphide; Method of removing — from gases. M. Mayer, Karlsruhe, Germany and A. Fehmann, Basel, Switzerland. U.S. Pat. 926,273, June 29, 1909.

THE gas is treated with a mixture of aniline or other suitable liquid amine and a metal oxide, or compound, in order to absorb carbon bisulphide. The spent mixture is then treated with a further proportion of the amine to cause the liberation of hydrogen sulphide.—W. H. C.

Purifying coal-gas and collecting by-products. T. Mc Watters, Hawkins, Station, Pa. U.S. Pat. 926,352, June 29, 1909.

THE gas at a temperature of about 300° F. is passed through a washer, whereby the temperature is reduced to from 90° to 70° F. and thick tar is condensed and collected separately. The gas is then passed through a condenser and the temperature further reduced to from 60° to 50° F. and strong ammoniacal liquor separated and collected. Any light tar or ammonia still remaining may be recovered from the gas by still further reducing its temperature.—W. H. C.

Phosphoretted hydrogen [in acetylene gas, etc.]; Process of rendering certain oxides and chlorides capable of absorbing —. Soc. Commerciale du Carburé de Calcium. First Addition, dated July 28, 1908, to Fr. Pat. 397,787, Mar. 6, 1908 (see Eng. Pat. 14,824, of 1908; this J. 1909, 237).

THE patent is for the use of a product containing cupric chloride or sulphate in place of a part of the mercuric chloride used according to the principal patent. As an example, the product may consist of 0.5 part of mercuric chloride, 4.5 parts of cupric chloride, 600 parts of ferric chloride solution of 45° B., 250 parts of ferric oxide, and 145 parts of dry infusorial earth.—A. T. L.

Acetylene; Purification of —. A. J. B. Jouve. Fr. Pat. 398,551, Jan. 15, 1909.

THE patent is for the use of persulphates for the purification of acetylene. These salts oxidise the impurities and are without action on acetylene itself.—A. T. L.

Automatic ignition of lighting gas; Process and apparatus for the preparation of a compound for —. C. Lubeck and M. Payet. Fr. Pat. 397,746, Mar. 5, 1908.

NATIVE hydrated cobalt oxide is mixed with cuprous chloride and heated *in vacuo* to 450° C., and a current of hydrogen or of lighting gas, previously heated to 120° C., is then passed over the mixture. The mixture is treated with hydrochloric acid so as to dissolve the cuprous chloride and to precipitate a double chloride of cobalt,

and copper, or a mixture of hydrated cobalt chloride and copper chlorides according to the conditions of the heating in hydrogen. The precipitate is allowed to settle on pieces of pumice stone which are afterwards dried. The solution is used for coating a part of the incandescent mantle, and the prepared pumice stone is made into pellets which are fixed near the burner.—A. T. L.

Incandescent electric lamps; Filaments for —. The British Thomson-Houston Co., Ltd., London, and H. H. Needham, Rugby. Eng. Pat. 23,726, Nov. 5, 1908.

THE claim is for the use of an alloy consisting of approximately 40 per cent. of cadmium, 40 per cent. of mercury and 20 per cent. of bismuth as a binder to mix with tungsten or other suitable refractory metal to form a "squirting mixture" from which the lamp filaments are pressed.

—W. H. C.

Filaments for electric and other incandescent lamps; Manufacture of — from tungsten and other refractory metals. O. E. Picquet. Fr. Pat. 398,010, March 12, 1908.

THREADS or fabrics of cotton or other fibre are impregnated with insoluble compounds of tungsten or other refractory metal, and the treated threads or fabrics are dried and heated in an atmosphere of hydrogen. The process of impregnation is carried out, in the case of tungsten, for example, by passing the threads alternately through a solution of a soluble tungstate and through an acid bath.

—A. T. L.

Incandescent lamps; Manufacture of flat metallic filaments for —. Deutsche Gasglühlicht Akt.-Ges. (Auerger.). Fr. Pat. 398,247, Jan. 2, 1909. Under Int. Conv., Jan. 2, 1908.

THE filaments are formed in the usual manner by squirting through circular orifices, and are then flattened by passing them between rollers. The flattened filaments are carbonised and finished in the ordinary way.—A. T. L.

Fuel for heating; Manufacture of —. T. Parker. Fr. Pat. 397,867, Aug. 5, 1908.

SEE Eng. Pat. 15,872 of 1907; this J., 1908, 930.—T. F. B.

Smoke; Apparatus for washing — and for inducing draught. J. Black, A. H. and H. Lennox. Fr. Pat. 398,394, Dec. 17, 1908.

SEE Eng. Pat. 14,693 of 1908; this J., 1909, 510.—T. F. B.

Producer-gas; Manufacture of —. W. J. Crossley, Openshaw, and T. Rigby, Fairfield, Manchester. U.S. Pat. 926,729, July 6, 1909.

SEE Eng. Pat. 28,181 of 1906; this J., 1908, 67.—T. F. B.

Gas from wood; Process of manufacturing —. B. Loomis, Hartford, Conn., and H. Pettibone, New Rochelle, N.Y., Assignors to Power and Mining Machinery Co. U.S. Pat. 927,418, July 6, 1909.

SEE Eng. Pat. 6302 of 1904; this J., 1904, 602.—T. F. B.

Gas producers; Generator for use with suction —, for use with bituminous or other coal. R. V. Farham. Fr. Pat. 397,985, Dec. 29, 1908.

SEE Eng. Pat. 5793 of 1907; this J., 1908, 326.—T. F. B.

Incandescence mantles; Refractory, indestructible filament for —. R. Laigle. Addition, dated March 19, 1908, to Fr. Pat. 382,749, Oct. 11, 1907.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Crude petroleum; Changes in — effected by diffusion through clay. D. T. Day and J. E. Gilpin. J. Ind. and Eng. Chem., 1909, 1, 449—455. (See this J., 1900, 890, 1005; 1908, 1105).

IN addition to unsaturated hydrocarbons, the asphaltic and sulphur compounds present in Texas petroleum are retained with great readiness when the oil is allowed to diffuse through clay (fuller's earth). Semi-solid paraffin hydrocarbons, on the other hand, are found in oils which have diffused so far through the clay as to become appreciably lower in specific gravity. It is suggested that the substances in colloidal suspension are retained by the clay more readily than those in true solution in the oil. This view is to some extent confirmed by partially successful attempts to precipitate asphaltum from its suspension in petroleum by addition of an electrolyte.—A. S.

Asphaltum in dark mineral oils; Use of "standard benzine" for the determination of —. Holde. Mitt. kgl. Materialprüfungsamt Gross-Lichterfelde West, 1909, 27, 143—148.

ASPHALTUM in dark mineral lubricating oils is determined by dissolving the oil in 40 times its volume of light petroleum, and separating the insoluble residue. The light petroleum to be used for this purpose is supplied by Kahlbaum, of Berlin, to a specification of a Committee of the German Union for Testing Technical Materials. This "standard benzine" is to be uniform as far as possible, free from unsaturated and aromatic hydrocarbons, with the sp. gr. 0.695—0.705 at 15° C.; at least 95 per cent. must boil between 65° and 95° C. Some analyses of the benzine supplied during the last few years are given in the paper; unsaturated and aromatic hydrocarbons are determined by shaking the benzine with fuming sulphuric acid, when the loss should not exceed 2 per cent. In testing successive batches on the same mineral lubricating oil, it was found that the asphaltum present in the latter increases slightly on keeping.

—A. G. L.

Gooch crucibles for asphalt analysis. Mears. See XXIII.

PATENT.

Use of creosote in internal combustion engines. Fr. Pat. 397,847. See 11.

IV.—COLOURING MATTERS AND DYESTUFFS.

iso-Indogenides. A. Wahl and P. Bagard. Compt. rend., 1909, 149, 132—134.

THE authors have prepared further examples of *iso-indogenides* (this J., 1909, 420*) by condensing oxindole with aromatic aldehydes in alcoholic solution in the presence of a trace of piperidine. *iso-Indogenides* from the following aldehydes are described: benzaldehyde, sulphur yellow needles, m. pt. 175—176° C.; anisaldehyde, yellow needles, m. pt. 157° C.; *m*-nitrobenzaldehyde, orange leaflets, m. pt. 255°—257° C.; *p*-dimethylaminobenzaldehyde orange yellow needles, m. pt. 194°—195° C.; this dyes wool in orange yellow shades; salicylaldehyde, yellow needles, m. pt. 195° C.; *m*-hydroxybenzaldehyde, yellow needles, m. pt. 280° C.; *p*-hydroxybenzaldehyde, small yellow crystals, above 300° C.; resorcyllaldehyde, small yellow needles, m. pt. above 300° C.; protocatechualdehyde, small compact crystals, m. pt. 246° C.; this dyestuff gives yellow shades on an aluminium mordant, a greenish-brown on iron, yellowish-brown on chromium, thallium, zirconium, and yttrium, and orange on titanium.

—J. C. C.

* In the above as in its original, for "Bayard" read "Bagard."

Tannic and gallic acids; Application of methods for the determination of — to extracts of various tanning materials. [Manufacture of inks]. F. W. Hürichsen and E. Kedesdy. Collegium, 1909, 233—237, 242—248.

IT has been previously shown that the content of tannic and gallic acids in iron-gall inks can be ascertained by acidifying the sample with hydrochloric acid, extracting with ethyl acetate, evaporating the extract *in vacuo*, and

weighing the residue. If necessary, the actual amount of tannic and gallic acids in the residue can be determined by titration with iodine solution or with copper sulphate solution, or colorimetrically by means of ammonium molybdate. Comparative experiments with extracts of gall nuts, myrobalauns, divi-divi, pine, oak, and mimosa, showed that with gall nuts, the evaporation residue of the ethyl acetate extract consisted wholly, and in the case of myrobalauns and divi-divi, mainly (from % - 1), of tannic and gallic acids. It extracts from which the portion insoluble in ethyl acetate had been removed, were used in the manufacture of inks, it would not be possible to detect, by chemical analysis, the substitution for gall nuts of other tanning extracts capable of giving a blue coloration with iron compounds. The German Official Regulation (Aug. 1, 1888), according to which, inks belonging to Class I, must be prepared from gall nuts, is thus valueless. Moreover Schluttig and Neumann have shown that inks prepared from extracts of myrobalauns, valonia, and sumac, and from hæmatoxylin are not inferior to those prepared with pure tannic acid with respect to intensity of colour and permanence of tint.

—A. S.

PATENTS.

Soluble blue for laundry and other purposes; Preparation of —. H. B. Binko and N. Mayer, London. Eng. Pat. 14,126, July 3, 1908.

ONE part by weight of indigo is treated with 4 parts of sulphuric acid and the solution is diluted with 16 parts of water. It is then filtered, and to the filtrate are added 4 parts of common salt and 2 parts of farina, dextrin, or gum. After standing for 3 days, the surplus water is drained off, leaving 16 parts of "soluble blue" paste. The paste, in addition to its use as a laundry blue, can be employed as printing ink for producing blue designs on cloth, metal, &c.—F. M.

Dyestuffs of the galloxyanin series; Manufacture of new blue to violet —. Chem. Fabr. vorm. Sandoz, Basle, Switzerland. Eng. Pat. 6272, Mar. 16, 1909. Under Int. Conv., Oct. 31, 1908. Addition to Eng. Pat. 6270 of 1909.

THE process described in the main patent for producing new dyestuffs by the action of resorcinol upon an alkaline solution of galloxyanin, may with advantage be carried out in the absence of air and taking one molecular proportion of resorcinol to two molecular proportions of galloxyanin. The product then consists of one molecule of the new condensation product and one molecule of leuco-galloxyanin; the latter can be recovered in a very pure condition.—P. F. C.

Tetrazo-dyestuffs; Production of new substantives —. Soc. pour l'Ind. Chim. à Bâle. Second Addition, dated Mar. 11, 1908, to Fr. Pat. 337,449, Dec. 5, 1903.

CLAIM is made for tetrazo-dyestuffs obtained from the tetrazo-compounds of diamines of the general formula,

O, S, --NH.CO. , $\text{--NH.CH}_2.$, $\text{--CH}_2.$, --O.CO.O. , --NH.CO.NH. , or --NHCS.NH. -groups and R and R' are identical or different radicals such as

The dyestuff prepared from the tetrazo-derivative of *pp*-diaminodiphenyl ether, $\text{NH}_2\text{C}_6\text{H}_4\text{O.C}_6\text{H}_4\text{NH}_2$, and 2:5-aminonaphthol-7-sulphonic acid in alkaline solution dyes cotton in bluish-red shades which become deep violet-blue when diazotised and developed on the fibre with β -naphthol. When *m*-aminobenzoyl-2:5-aminonaphthol-7-sulphonic acid is used, the resulting dyestuff gives blue-red shades on cotton which on further treatment as above turn to a bright scarlet. The tetrazo derivative of thioaniline gives, with 2:5-aminonaphthol-7-sulphonic acid, a dyestuff dyeing cotton in blue-red shades which become violet on diazotisation and development with β -naphthol on the fibre. *m*-Aminobenzoyl-*m*-phenylenediamine (prepared by condensing *m*-nitraniline with *m*-nitrobenzoyl chloride and reducing the product) gives, when tetrazotised and combined with 2:5-amino-

naphthol-1:7-disulphonic acid in alkaline solution, dyestuff producing orange shades on cotton, and on diazotising and developing on the fibre with β -naphthol a pure blue-red is obtained. The same tetrazo-compound when combined with *m*-aminobenzoyl-2:5-aminonaphthol-7-sulphonic acid gives a dyestuff producing red shade on cotton passing into red-orange on further treatment on the fibre. The mixed disazo-dyestuff, obtained from the same tetrazo-compound and one molecular proportion of 2:5-aminonaphthol-7-sulphonic acid and one *m*-aminobenzoyl-2:5-aminonaphthol-7-sulphonic acid dye cotton in red shades passing into a brownish Bordeaux on further treatment on the fibre.—J. C. C.

Fat dyestuff; Process for preparing a red — either as such or on the fibre or on another substratum. Gea. 1 Chem. Industrie in Basel. Ger. Pat. 211,696, Nov. 5, 1907. Addition to Ger. Pat. 205,377, Jan. 17, 1907.

THE process is similar to those described in the original patent (see Eng. Pat. 344 of 1908; this J., 1908, 399) and in Ger. Pat. 210,813 (this J., 1909, 790), except that acenaphthenequinone is applied in the form of its bisulphite compound, and is heated with 3-oxy-(1)-thio naphthene or its 2-carboxylic acid, in aqueous solution or suspension, with addition of alkali, either alone or in presence of fibres or fabrics or substrata suitable for lake-formation. T. F. B.

Chlorotoluidinesulphonic acid; A new —, and process of preparing dyestuffs therefrom. Badische Anilin und Soda Fabrik. Fr. Pat. 398,602, Jan. 18, 1909. Under Int. Conv., Nov. 26, 1908.

2-ACETYLAMINO-1-METHYLBENZENE-5-SULPHONIC acid is mixed with water and chlorine passed in at 0° C. Hydrochloric acid is then added and the whole boiled in order to remove the acetyl group. 3-Chloro-2-amino-1-methylbenzene-5-sulphonic acid separates as a pale red crystalline precipitate. When this new acid is diazotised and combined with β -naphthol, an orange dyestuff is obtained which gives a yellowish-orange lake with barium chloride. On condensing sodium dioxycarbonate with 3-chloro-2-hydrazino-1-methylbenzene-5-sulphonic acid in aqueous solution, the resulting dyestuff as well as the lakes prepared from it furnish very pure citron yellow shades. When 3-chloro-2-amino-1-methylbenzene-5-sulphonic acid is diazotised and combined with 1-*p*-sulphophenyl-5-pyrazolone-3-carboxylic acid in alkaline solution, a dye stuff is produced which dyes wool in pure yellow shades.—J. C. C.

Fat dyestuff of the anthracene series; Process for preparing a red —. Badische Anilin und Soda Fabrik. Ger. Pat. 211,383, July 21, 1908.

BY treating the sulphonic acid of 2-aminoanthraquinone (obtained by sulphonation with fuming sulphuric acid with acid oxidising agents, a dyestuff soluble in water which dyes red shades from the vat, is produced. It is quite different from the green dyestuff obtained by sulphonating the oxidation products of 2-aminoanthraquinone.—T. F. B.

Colouring matters of the anthracene series; Manufacture of —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine Germany. Eng. Pat. 24,604, Nov. 16, 1908.

SEE Fr. Pat. 396,583 of 1908; this J., 1909, 596.—T. F. B.

V.—PREPARING, BLEACHING, DYEING, PRINTING AND FINISHING TEXTILES, YARNS, AND FIBRES.

Silk; The world's trade in —. Zeits. Seide, 14, 324; Z. angew. Chem., 1909, 22, 1474.

THE total consumption of silk is estimated at 25 million kilos. Ten years ago the consumption was 15 million kilos, nearly all in Europe, since at that time America imported very little raw silk, but acquired the manufactured material from Europe. The production has increased only slightly in Europe, but to a greater extent in China and Japan, the latter country producing about half as much again as 10 years ago. The most important increase has however taken place in Asia Minor, which supplies now practically the whole of the European imports, whilst the Japanese exports go almost exclusively to America, which country now no longer supplies its market with European silk, but buys as much raw silk as did the whole of the world together 15 years ago.—A. S.

PATENTS.

Dyeing machines and the like. J. T. Hanson, Huddersfield. Eng. Pat. 13,226, June 22, 1908.

IN dyeing machines of the "Rhodes" type in which wool, yarn, or other fibrous material is supported during treatment upon canvas or wire gauze, the canvas or gauze is kept clean only with difficulty. It is therefore proposed to construct the false bottom in the form of a grating, of parallel iron bars, the bars being wider at the top than at the bottom.—F. M.

Dyeings on furs, hairs, feathers, etc.; Process for producing dark brownish-red —. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 211,567, July 20, 1907.

FURS, hairs, feathers, and similar articles, mordanted or not, are treated with a solution of nitro-*p*-phenylene-amine in presence of an oxidising agent, such as hydrogen peroxide. Without mordants, Bordeaux-red shades are produced, whilst with mordants various shades of brownish to black-brown are produced.—T. F. B.

Reserves under Thioindigo Red, indigo, and sulphide dyestuffs; Process for producing —. Kalle und Co., A.-G. Ger. Pat. 210,682, May 23, 1906.

WHITE or coloured reserves under thioindigo, indigo, or sulphide dyestuffs are obtained by printing the material with a thickened aromatic nitro-compound, which is efficiently soluble in water or the thickening mixture, drying, and then padding or printing with an alkaline mixture containing Thioindigo Red, indigo, or a sulphide dyestuff, and finally steaming and washing. As an example of a white reserve under Thioindigo Red, the following mixture is given:—100 grms. of sodium *o*-nitrotoluenesulphonate, 800 grms. of gum solution (1:1), and 100 grms. of water.—T. F. B.

Canned fabric with finish coating and process of making same; Artificial —. E. Weinheim, New York. U.S. Pats. 926,525, 926,526, and 926,527, June 29, 1909.

A SOFT fluffy pad of vegetable fibres is impregnated with a solution of potassium bichromate and dried. A "leather-

fyng" composition, containing viscous animal matter, vegetable oil, animal fat, a hydrocarbon, a metallic oxide, and a saponifying agent, is then forced into it under continued pressure and heat. The composition coagulates and the fibres are thus covered with an insoluble coating. The fabric is next dried and a layer of the composition suitably coloured, is applied to its surface and subjected to heat and pressure to render it insoluble. The material thus obtained may be finally varnished and calendered.

—P. F. C.

Bleaching; Process of —. F. Fuhrmann, Assignor to L. F. Neirath, Berlin. U.S. Pat. 927,457, July 6, 1909.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Sodium 4/3-carbonate. J. Habermann and A. Kurtenacker. Z. anorg. Chem., 1909, 63, 65—68.

BESIDES the normal carbonate and bicarbonate, two other carbonates of sodium have been described in the literature, namely the sesquicarbonate, $\text{Na}_2\text{CO}_3 \cdot 2\text{NaHCO}_3 \cdot x\text{H}_2\text{O}$, and the 4/3-carbonate, $\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$. Natural soda was formerly supposed to consist of the sesquicarbonate, but Chatard (Amer. J. Sci., [3], 38, 59) found that American trona had a composition corresponding to the 4/3 carbonate, and stated also that the methods prescribed for the preparation of the sesquicarbonate always gave the 4/3 carbonate together with some bicarbonate. In the authors' experiments, a solution of sodium bicarbonate, saturated in the cold, was boiled in a flask through which a strong current of air was passed, until crystals began to separate. The residue was dissolved in a small quantity of water, and hot 96 per cent. alcohol added until a turbidity was produced. On cooling, leaflets of normal sodium carbonate separated. The mother liquor, when again treated in a similar manner with alcohol, yielded needle-shaped crystals of the 4/3-carbonate. The same product was also obtained by leading carbon dioxide into a boiling solution of normal sodium carbonate until crystals began to separate, and then treating with alcohol as before. The authors therefore conclude that the 4/3-carbonate is the only one intermediate between the normal carbonate and the bicarbonate, which is capable of existence or at all events which can be isolated. A carbonate of potassium corresponding to sodium 4/3-carbonate is not produced under analogous conditions.

—A. S.

[But, according to Deville and Divers, J. Chem. Soc., 1870, 23, 190, the corresponding ammonium salt can be obtained in this way.]

Potash Syndicate; Renewal of German —. Oil, Paint, and Drug Rep., Aug 2, 1909. [T.R.]

THE German potash syndicate has been provisionally renewed until Dec. 31st, 1910. The acquisition of the Solldstedt and Aschersleben mines by the International Agricultural Corporation of America created some difficulty, and the Syndicate opened negotiations for taking over the contracts, at the same time letting it be known that, if the Syndicate were not renewed, the German Government would levy an export duty on potash equivalent

to about £4 a ton on concentrated salts. This apparently had the desired effect, but the position is one of great uncertainty.

Potassium carbonate; Hydration of —. De Forcrand. *Compt. rend.*, 1909, **148**, 1731—1734.

AFTER referring to the uncertainty existing with respect to the different hydrates of potassium carbonate, and hence the lack of precision in the use of this salt as a dehydrating agent, the author shows that from saturated solutions the hydrate with 1.5 mols. of water separates at all temperatures between 10 and 75° C., and also from the solution saturated at 130° C., when cooled to 75° C. The crystals when apparently dry contain 1.62–1.99 per cent. of water, but they yield a moist powder, which after being dried in a current of inert gas at 30° C., contains 1.5 mols. of water. The saturated solution of the hydrate at 15° C. has the composition, $K_2CO_3 \cdot 7.2H_2O$, and the sp. gr. 1.57. When heated in a current of inert gas at 100° C., the hydrate gradually loses the whole of its water, without any indication of the formation of a hydrate with 1 or 0.5 mol. of water. The heats of solution (at 15° C.) of anhydrous potassium carbonate, of the hydrate, $K_2CO_3 \cdot 1.5H_2O$, and of the saturated solution, $K_2CO_3 \cdot 7.2H_2O$, are +6.382, –0.654, and –0.020 cal., respectively, so that on passing from the anhydrous salt or the hydrate to the saturated solution, the thermal effect is +6.402 cal. in the first case, and –0.634 cal. in the second. Hence, the hydrate is of no use as a dehydrating agent, and in order to obtain the greatest effect with the anhydrous salt, such a quantity should be used as will yield the hydrate with 1.5 mols. of water.—A. S.

Nitrates; Detection of small quantities of — in presence of bromides. Villedieu. *J. Pharm. Chim.*, 1909, **30**, 66—67.

FROM a mixed solution of nitrates and bromides, the latter are precipitated almost completely as lead bromide by means of excess of solution of basic lead acetate. After filtering, the excess of lead is removed by means of sodium sulphate. After again filtering, the filtrate is treated with an equal volume of sulphuric acid. This acid liquid affords the usual reaction for nitrates with ferrous sulphate and sulphuric acid, and other reactions for nitrates which are obscured by the presence of bromine.—J. O. B.

Perchlorates; Reduction of — by titanium sesquisulphate. A. Stähler. *Chem.-Zeit.*, 1909, **33**, 759.

ACCORDING to the author, perchlorates cannot be determined satisfactorily by boiling in sulphuric acid solution with titanium sesquisulphate solution, and titrating the excess of trivalent titanium left, as, even when the whole operation is carried out in an atmosphere of carbon dioxide, appreciably more titanium is oxidised than corresponds with the perchlorate. Good results are obtained, however, if the chloride formed is determined. The author deems it incorrect to apply the term "titanous salts" to salts of trivalent titanium. Titanous salts are salts of bivalent titanium, which have recently been prepared in aqueous solution by the author and H. Georges.—A. G. L.

Lead phosphates; Contribution to the knowledge of —. H. Alders and A. Stähler. *Ber.*, 1909, **42**, 2261—2270.

STÄHLER and SCHARFENBERG (Ber., 1905, **38**, 3869), asserted that the precipitate caused by solutions of sodium phosphate in aqueous solutions of lead salts at ordinary temperatures, consists of mixed crystals, and that the mixture becomes homogeneous when boiled with water, tribasic lead phosphate being formed. The authors have now prepared three distinct phosphates of lead, and establish the fact that it is impossible to prepare pure lead phosphate by precipitating a solution of a lead salt with excess of alkali phosphate at ordinary temperatures, since under these conditions the precipitate always includes a considerable quantity of alkaline salt not removed by boiling with water. *Tribasic lead phosphate*, $Pb_3(PO_4)_2$, is prepared either by precipitating an excess of lead acetate with a small quantity of sodium phosphate at 100° C., or by boiling the dibasic salt in water for 5–6 hours. The compound obtained in either case, forms an amorphous white powder. *Dibasic lead phosphate*, $PbHPO_4$, is

readily prepared by precipitating a somewhat dilute solution of lead nitrate with hot dilute phosphoric acid (about 25 per cent. H_3PO_4), at 100° C. The compound separates as a fine crystalline powder. The dibasic salt entirely converted into the tribasic compound by prolonged boiling with water, the crystals of the former suffering disruption. *Monobasic lead phosphate*, $Pb(H_2PO_4)_2$, prepared in the pure state by dissolving the dibasic salt in concentrated phosphoric acid (90 per cent. H_3PO_4), with the aid of heat, and allowing the solution to crystallise. A recrystallisation from phosphoric acid frees the compound from traces of the dibasic salt. The salt forms fine needles, stable in air. It is decomposed by cold, very readily by boiling water, forming first the dibasic, and finally the tribasic salt. The tribasic salt is only stable at a very low concentration of phosphoric acid, the dibasic salt already beginning to form in the presence of 0.046 per cent. of phosphoric acid. The dibasic salt possesses the greatest stability in the presence of free phosphoric acid. The monobasic salt is only stable in the presence of highly concentrated acid, slight alterations in the degree of concentration sufficing to determine its conversion into the dibasic salt.—E. C. V. E.

Bismuth bromide; Hydrolysis of —. R. Dubriay. *Compt. rend.*, 1909, **149**, 122—124.

PURE bismuth bromide was prepared by igniting crystallised bismuth nitrate, and dissolving the resulting oxide in hydrobromic acid free from bromine. This liquid was treated with water under various conditions, and the various phases were determined by precipitating the bismuth as sulphide, and titrating the free hydrobromic acid with alkali, using methyl orange as indicator. The author found: (1), that increase of temperature had no appreciable effect on the hydrolytic dissociation of bismuth bromide; (2), representing graphically the contents of bismuth and of hydrobromic acid under different conditions of hydrolysis, a continuous curve was obtained, from which the phase rule indicated that only one bismuth oxybromide had been precipitated in the course of the experiments.—O. R.

Chromic oxide; Red colloidal solution of —. H. W. Wondstra. *Z. Chem. Ind. Kolloide*, 1909, **5**, 33.

CHROMIC hydroxide was dissolved in acetic acid, the solution evaporated to dryness at 40° C. *in vacuo*, the residue dissolved in water and the solution dialysed. The liquid finally obtained appeared clear and brown-red in transmitted light, and dirty-green in reflected light. On passing an electric current through the liquid, it was shown to be electropositive. The red colour disappeared from the vicinity of the positive electrode, a lilac tint taking its place. A second solution of chromic hydroxide was obtained by dissolving this substance in acetic acid and steam-distilling the solution until a green precipitate was produced. The liquid was then diluted with cold water and filtered after some time. The filtrate showed properties similar to those of the first solution, but was coagulated by an electric current, green flocks being produced. Neither solution was coagulated by adding electrolytes. Acids merely produced green solutions of chromium salts.—A. G. L.

Iodine; Determination of — gravimetrically by the action of metallic silver. F. A. Gooch and C. C. Perkins. *Amer. J. Sci.*, 1909, **28**, 33—39.

IODINE may be determined gravimetrically, either in a neutral solution or in a solution made alkaline with a bicarbonate, by shaking the solution with metallic silver, in the presence of potassium iodide, in a closed flask filled with hydrogen, and determining the increase in weight of the silver. The best form of silver, and the one most easily prepared in the pure state, is that deposited electrolytically, upon a small oscillating cathode of platinum, from a solution of silver nitrate, the platinum anode being enclosed in a porous cell. The flask containing a weighed quantity of silver is shaken, so as to give the liquid a rotary motion, until the colour due to iodine vanishes (15–25 mins. for 0.65 grm. of iodine in 50 c.c. of liquid); the liquid is then diluted and filtered

rough a Gooch crucible, and the residue of silver and
 Iver iodide washed, dried at 130°—140° C., and weighed.
 —F. SODX.

PATENTS.

caustic alkali; *Process for the electrolytic manufacture
 of — with simultaneous obtaining of bromine.* H.
 Kossuth. Ger. Pat. 211,068, Jan. 23, 1908.

THE process consists in using an alkali chloride solution
 of catholyte and a solution containing both chlorides and
 bromides, e.g., the final liquors from the manufacture
 of potassium chloride, as anolyte. By suitably regulating
 the flow of the anolyte in accordance with its content of
 bromides, no chlorine, but only bromine is produced at
 the anode.—A. S.

Lapiesite in the form of an impalpable paste or powder;
*Manufacture of —, and of calcined magnesite there-
 from.* J. Leese, Manchester. Eng. Pat. 612, Jan. 11,
 1909.

THE process is based on the discovery that "amorphous"
 distinguished from "crystalline" magnesite is com-
 pletely disintegrated by treatment with a comparatively
 small quantity of acid diluted sufficiently to wet the whole
 of the rock. The proper quantity of acid to be used
 must in each case be determined by preliminary experi-
 ment, but at least 1 fluid oz. of liquid must be present
 for every 4 oz. of magnesite. The magnesite is used in
 the form of lumps. When all the acid added has been
 neutralised, water is added to the mass, and the magnesite
 is run out in the form of a "milk" from the decomposition
 vessel, in which any grit remains behind, this "milk"
 is run on to filters, washed and dried at a temperature
 not exceeding 150° C. Or else, it is ignited to form
 magnesia. Hydrochloric, nitric, or sulphuric acid may
 be used for the decomposition; hydrofluoric acid or a
 soluble fluoride may be added in cases in which it is
 desired to remove silica.—A. G. L.

Hydrated magnesia; *Process of preparing concentrated*
 —. W. S. Morrison, Oakland, Cal. U.S. Pat.
 926,280, June 29, 1909.

THE claim is for the process of preparing a concentrated
 magma of magnesium hydroxide which has been thoroughly
 freed from the precipitating reagent and consists in mixing
 the magma with water, boiling, agitating, settling and
 draining off the water each day for several successive
 days. Finally the strained mass is concentrated by
 heating with constant agitation. The product should
 be an unctuous, moist and plastic mass, free from grit-
 tiness, having a specific gravity of about 1.13 and the
 individual particles forming the magma should measure
 from 1/5000 to 1/10,000 of an inch in diameter.—W. H. C.

Chlorine; *Method of causing — to act on liquids or
 suspensions which are to be chlorinated or oxidised.*
 E. A. F. Düring. Ger. Pat. 211,066, July 29, 1908.

THE direct use of liquefied chlorine in the preparation of
 hypochlorites, etc., has been accompanied with great
 difficulties. These are claimed to be overcome by the
 process described. The liquid or suspension to be treated
 is kept in vigorous motion in a closed vessel, and the
 liquefied chlorine is introduced in the form of a fine rain
 through jets which do not come in contact with the liquid.
 The way of carrying out the process is to circulate the
 liquid to be treated continuously through a closed tower,
 provided with plates, balls, or the like to assist the distri-
 bution, and introduce the liquefied chlorine through fine
 jets projecting laterally into the tower.—A. S.

Water-glass; *Process of increasing the mobility and
 reactivity of — by means of chemical admixtures.*
 R. Elberhard, Munich, Germany. Eng. Pat. 13,792,
 June 29, 1908. Addition to Eng. Pat. 12,980, June 17,
 1908.

VIII.—GLASS, POTTERY, AND ENAMELS.

Clay; *Liquefaction of — by alkalis, and use of fluid clay
 casting in the ceramic industry.* E. Weber. Trans.
 Eng. Ceram. Soc., 1908-9, 8, 1—22.

THE plasticity of clay is probably due to colloidal
 substances, organic as well as inorganic. These colloids,
 such as aluminium hydroxide, iron oxide, silicic acid,
 and humic compounds, can exist in solution as well as in
 a gelatinous condition, so that the plasticity of clay may
 be destroyed by dissolving the colloids. This can be
 effected by adding small quantities of alkali, but the process
 is retarded by the quantities of salts, especially sulphates,
 which a clay can absorb, and which precipitate the colloids.
 When this difficulty is overcome, it is possible to cast
 sanitary and fireclay goods of great size and thickness,
 despite the coarsely powdered and specifically heavy
 substances such as grog, shale, quartz, corundum, which
 are added to fireclay. To obtain the requisite fluidity,
 each clay must be treated on its own merits. The appli-
 cation of heat may be serviceable in some cases, whilst
 with other clays, which contain much colloidal silicic acid,
 the colloids are gelatinised on heating. Casting is very diffi-
 cult with some clays because they gelatinise immediately
 they are at rest in the mould, so that the superfluous
 material cannot be removed without damage to the slip
 or to the mould. Where this gelatinisation cannot be
 rectified chemically, it is necessary to increase the propor-
 tion of water, whereas a good casting slip should contain
 very little more water than is needed for pressing or
 throwing; that is, about 15 to 20 per cent. The plaster
 mould absorbs the greater part of the alkalis used for
 liquefaction, hence the influence of alkalis on the refractory
 qualities of the ware need not be feared. The water and
 alkalis may be removed from the slips quickly by electro-
 osmosis. The bottom is connected with the negative
 pole, and the top with the positive pole of a source of
 current, and a very small current is sufficient to cause the
 water and alkali to collect at the bottom. In this way
 clay slips can be very quickly dried. Liquefaction is best
 effected by means of sodium and potassium hydroxides,
 ammonia, and the sodium, potassium, and ammonium
 salts of weak acids, such as carbonic, phosphoric, oxalic,
 and boric acids. The salts of the stronger acids (sulphuric,
 nitric, hydrochloric, and acetic acids, etc.) retard lique-
 faction. Of the divalent bases, those soluble in water,
 e.g., barium and calcium hydroxides, precipitate colloids,
 though under certain conditions they may influence
 liquefaction favourably. Vigorous stirring is essential in
 all cases. This new method of casting has been in use for
 four years. It can be used for the manufacture of blocks
 for glass and gas furnaces, locomotive boxes, retorts and
 zinc muffles. Attempts are now being made to cast the
 large crucibles used in the manufacture of steel, which hold
 twenty tons of molten metal, in one piece.—H. H. S.

Enamels; *The function of fluorine compounds in —.*
 M. Mayer and R. Hays. Chem. Zeit., 1909, 33, 758.

THE authors criticise Bock's work (this J., 1908, 900).
 Comparison of the analyses of finished enamels with the
 composition calculated from the ingredients used, shows
 that a large part of the fluorine added remains in the
 enamel. Thus, for two enamels, one containing 51, the
 other 65 per cent. of silica, to which 6.8 and 4.8 per cent.
 of calcium fluoride were added, the losses of fluorine after
 melting amounted to only 20.2 and 23.8 per cent.

respectively. In another case, in which cryolite as well as fluor spar was added, only 11.85 per cent. of the total fluorine was volatilised. Cryolite possesses the power of clouing enamels, and can replace tin oxide to a large extent for this purpose. The authors confirm Ruff and Plato's experiments, according to which the melting-point of fluor spar is above 1400° C., and not, as recently stated by Vogt, about 900° C.—A. G. L.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Fireclay goods; Glazing of porous — A. B. Searle. Trans. Eng. Ceram. Soc., 1908 9, 8, 31—45.

Bricks and tiles are the simplest forms of glazed fireclay articles; more complicated is a lavatory basin with a back of more than four inches, while a bath is the most difficult of all. When separate pieces have to be fitted together, it is important, for uniformity in colour, to have them as large as possible, so that the number of separate pieces is reduced to a minimum. It is less easy to glaze a brick made of compressed dust than one made of the same clay by the plastic process. Re-pressing of "finished" goods before glazing is not necessary, though in the case of bricks it is the simplest method of giving them a good shape and surface. The pressures used are often excessive. The best size of grain of the body depends chiefly on the nature of the firing. Sometimes it is advantageous to use a larger proportion of grog ground up a little more finely. The clays of the Southern Midlands do not take the glaze in the green state (without previous biscuiting) so well as the northern clays. The latter, if biscuiting before glazing, give a very rough surface. The glazed bricks and wall-facings of the future will probably be composed of a more or less vitrified body, but goods of this class cannot be regarded as fireclay, and are not porous. At present, most manufacturers favour a porosity as high as 15 per cent. With regard to the glaze, it is more important in building ware that it should not craze than that it should be free from lead. Seger's formula for white-ware glazes is, $RO, 0.1-0.4Al_2O_3, 2.5-1.5SiO_2$, and for porcelain glazes, $RO, 0.5-1.25Al_2O_3, 5-12SiO_2$. For leadless glazes on bricks and sanitary ware fired at 1300° C., the author suggests the formula, $RO, 0.9-1.1Al_2O_3, 5-7SiO_2$. These glazes are not simple silicates, but the replacement of part of the lime by barium sulphate enabled a firm to use a glaze which had a rational formula with whole numbers instead of fractions. Such glazes, however, cause devitrification, though they are useful when crystalline effects are wanted. The engobe, the slip placed between the body and the glaze, is generally most satisfactory when its composition is the arithmetical mean of the compositions of body and glaze. The excessive grinding of glazes has a detrimental effect on their adhesive power in the kiln, causing "curling." Colouring oxides cannot be too finely ground, but for most purposes the glaze need only be fine enough to pass through a No. 200 sieve.—H. H. S.

Heat-insulating materials; Efficiency of — C. R. Durling. Engineering, 1909, 88, 37—38.

A NUMBER of commercial laggings have been tested with the apparatus previously described (this J., 1907, 1297), and curves are given showing the relation between the amount of heat escaping per sq. ft. per hour and the internal temperature of the apparatus. With material intended for steam-pipe or boiler coverings, the outer surfaces were exposed to convection and radiation, in order to imitate practical conditions, it being pointed out that conductivity tests, in which the material is placed between two surfaces, give results which apply only to enclosed laggings, as used in cold stores, etc., the loss of heat through a lagging with exposed surface being

upwards of 10 per cent. greater. A comparison of the results with different thicknesses of the same lagging shows, that at low temperatures the saving effected by the use of a thicker lagging is much less marked than at high temperatures; also, at a given temperature, the additional saving effected by successive increments of thickness is a diminishing quantity, the economic limit under given conditions, being readily ascertained by comparing the extra saving, as shown by the curve and the cost for successive thicknesses. The insulating power of some materials, such as magnesite and blue asbestos fibre, is found to improve as the temperature is increased, and it is quite possible for a material at low temperatures to give results inferior to those obtained with another material and yet to be superior to the other at high temperatures, a point of importance in selecting a lagging for pipes conveying highly superheated steam. A curve is also given for a slag-wool lagging, illustrating the fact that a porous solid is a better insulator than an air-space or the same material in a non-porous form, and it is recommended that in all cases the most suitable density should be determined experimentally.—F. SODS

Hydraulic cements; The setting of calcareous — W. Michaelis, sen. Z. Chem. Ind. Kolloide, 1909, 5, 9—22.

THE hardening of hydraulic cements is, according to the author, due entirely to the formation of colloidal compounds practically insoluble in water. Of these compounds calcium silicate is by far the most important, calcium aluminates and ferrites playing similar but very subsidiary rôles. On gauging Portland cement with water, a saturated solution of calcium hydroxide, aluminate, ferrite and sulphate is obtained almost at once, from which needle-shaped crystals are soon deposited, as the water necessary for solution is taken up by adjacent particles of the cement. So far the process is analogous to the setting of plaster of Paris, and, if the hardening of cement consisted solely in this, the resulting mass of crystals consisting of the compounds mentioned above, to which calcium carbonate and calcium sulphoaluminate are added later, would be as little resistant to the prolonged action of water as plaster is. The cement particles, however, which have become deprived of lime, and made richer in acid substances by this process, soon begin to take up lime and water again from the strong solution of calcium hydroxide surrounding them, with formation of hydrated colloidal calcium silicate, aluminate and ferrite. The water is given up again by these hydrated colloids to fresh particles of cement; the lime remains adsorbed. As more lime is taken up, whilst water is lost, the hydrated colloids set to firm and hard colloids and this process constitutes the true hardening of hydraulic cements. The whole process can be watched under the microscope, as described by Le Chatelier, Ambronn, and others.

A number of direct experiments are adduced in support of the above theory. Thus, Portland cement treated with a large quantity of water and prevented from setting by shaking, loses lime until approximately monocalcium compounds of silica, etc., are left. If this leached cement is then shaken with a saturated solution of lime-water, a small quantity of lime is taken up, and the particles swell enormously in size. If, on the other hand, the leached cement is cautiously covered with the saturated lime-water, so as not to disturb the particles, lime is also taken up, a marked change in colour from brown to white takes place, but instead of swelling, the particles become firm and set together.

Magnesia is a practically inert substance in cement, since its solubility in water (1 in 55,000 parts) is too small to allow of the formation of a solution sufficiently basic to enable the silica to withdraw it from solution and so to form colloidal magnesium silicate. The presence of alkalis in general delays the setting of cement, as they tend to form soluble silicates. Alkali carbonates also delay the setting by precipitating inert calcium carbonate as fast as the lime goes into solution, and thus delaying the formation of the strong solution of calcium hydroxide necessary. The action of other substances is explained on the same lines.—A. G. L.

silicofluorides and Portland cement. M. Merkulow. Ingenieur, 1909, 28, 114; Tonind.-Zeit., 1909, 33, 871—872.

CUBES (7×7×7 cm.) of normal Portland cement mixed in different proportions of sand were allowed to harden for 2—3 days, and then repeatedly immersed for 2—5 hours in a solution of zinc silicofluoride (zinc "fluoride"), after drying for at least 24 hours, the treated cubes were kept in air or water for different periods, or repeatedly frozen, and the compression tests obtained compared with those furnished by similar cubes not treated with the silicofluoride solution. The results obtained are summarised in the following table, the results being stated in per cent.

Treatment.	Mixture 1:1.		Mixture 1:2.		Mixture 1:3.		Mixture 1:4.	
	Treated.	Untreated.	Treated.	Untreated.	Treated.	Untreated.	Treated.	Untreated.
days in air.....	147	132	133	114	103	59	54	25

frozen 23 times.....	204	136	166	121	94	67	43	22

[Note:—1 kilo per sq. cm. = 14.2 lb. per sq. in.]

Treated and untreated cubes of the 1:3 mixture were so allowed to harden for 14 days in air, and then tested by Bauschinger's abrasion method, the disc making 200 revolutions. Three treated cubes, with an initial weight of 768—777 grms. lost 27—42 grms. by this treatment; three similar untreated cubes, weighing initially 740—743 grms., lost 318—321 grms. It is evident that the treatment increases the resistance to compression, and the hardness, of the cubes considerably.—A. G. L.

Portland cement; Decomposition of —. W. Muth. Tonind.-Zeit., 1909, 33, 841—842.

CEMENT was treated with varying proportions (from 2½ to 800 times by weight) of water, and prevented from setting by shaking continually at first. The phenomena which occurred are described in detail and practically confirm Imbronn's observations (this J., 1909, 366). When a large excess of water is used, needle-shaped crystals are reduced first, accompanied by a large increase in the volume occupied by the cement; later on a small quantity of a colloid is also formed. As the quantity of water used is decreased, the quantity of these crystals produced diminishes, as does also the increase in volume, whilst at the same time the quantity of colloid formed increases. The author concludes that only the colloid plays a part in the setting of cement, and that the formation of crystals of calcium hydroxide and of the needle-shaped crystals observed can be of importance only as regards the final hardening of the cement.—A. G. L.

Cement; CO₃'-ions; Retardation of reactivity of adsorbed —. P. Rohland. Z. Chem. Ind. Kolloide, 1909, 5, 33—35.

HEX Portland cement is digested for some time with a solution of an alkali carbonate or bicarbonate, the cement being prevented from setting by shaking or stirring, it absorbs the CO₃'- or HCO₃'- ions completely. On removing the alkali solution, and treating the cement with dilute hydrochloric acid, it is found that no evolution of carbon dioxide occurs until the concentration of the acid is increased so much that the cement dissolves as a whole. The acid ions taken up from ammonium carbonate solutions are held less firmly, and can be detected by treatment with 2N-hydrochloric acid. Cement also takes up the acid ions from solutions of borax. The author believes that these phenomena are connected with the tenacity with which sodium sulphate is retained by glass or by medium-hard-burnt bricks, long-continued extraction of the finely powdered material with water being necessary in these cases to remove the sodium sulphate.—A. G. L.

Graphite crucibles for asphalt analysis. Mears. See XXIII.

PATENTS.

Resinous cement; Process for the production of moulded masses [artificial stones, ore briquettes, etc.] by binding and hardening filling materials by —. A. Hol, Witten-Ruhr, and A. Pieper, Schmalleberg, Germany. Eng. Pat. 14,954, July 14, 1908.

IN the production of artificial paving stones, ore briquettes and the like, the filling material, for example, stones, blast-furnace slag, ore-dust, etc., is heated to remove all the moisture, and whilst still hot is mixed with a hydrocarbon solvent for the resinous binding material, such as asphaltum, which is then added and thoroughly mixed with the impregnated filling material. When thoroughly mixed, the mass is heated for some time to bring about polymeri-

sation of the solvent, so that it acquires properties similar to the resinous binding material, and no longer exists as a separate solvent body. The claims also include the moulded mass obtained from filling materials, resinous cements and hydrocarbon solvents, which solvents are finally polymerised, and objects manufactured from the mass. —W. C. H.

Cement; Manufacture of [white] —. T. D. Kelly. Forest Gate. Eng. Pat. 14,336, July 6, 1908.

FLINTS are heated to redness, and plunged into cold water. One part of the powdered silica so obtained is mixed with 2—4 parts of chalk or lime and 10—15 per cent. of common salt, and the whole calcined, a white clinker being obtained if contact with the fuel is prevented. Alternatively, clay is treated first with hydrochloric acid and then washed with water. One part of the leached clay is mixed with 2—4 parts of chalk or lime and about 10 per cent. of salt, and the whole burnt to cement. Instead of washing the clay with hydrochloric acid, this operation may be omitted, and then a larger proportion of salt (10—15 per cent. in excess of the quantity of ferric oxide present) must be used in order that the iron may be volatilised during the burning.—A. G. L.

Disposal of house refuse. Eng. Pat. 23,765. See XVIII B.

X.—METALS AND METALLURGY.

Iron and steel; Transformations of —. Grenet. Bull. Soc. Chim., 1909, 5, 758—764.

THE author combats the view that the transformation of pure iron is a phenomenon to be considered apart from the mutual solution of iron and carbon. He extends the idea of solid solution to pure bodies and considers the transformation of pure iron as a limiting case, the passing of pure iron into solid solution, just as the fusion of a pure body may be regarded as the limit of its liquid solution in other constituents, when the proportion of these approaches zero. Steels are looked upon as containing only the three constituents, ferrite, cementite, and solid solution, and the phenomena relating to them as falling in with the general case of alloys, of which the constituents can form solid solutions at certain temperatures. The law relating to the phenomena of quenching and annealing becomes general, therefore, and may be stated: an alloy, formed of several constituents, is softer, as the maximum temperature attained since the transformation which has given rise to these constituents becomes higher and

longer maintained. The quenching (rapid cooling) of an alloy, heated to a sufficiently high temperature for its constituents to form a solid solution, may lower the temperature at which the solid solution decomposes into its constituents, in which case quenching will cause hardening, or it may suppress the transformation on cooling, when the effect of quenching cannot be foreseen.

—F. SODN.

Cementation of iron by carbon in vacuo. L. Guillet and C. Griffiths. *Compt. rend.*, 1909, **149**, 125–127.

SUGAR charcoal, which had previously been heated in chlorine to 1000° C., and soft iron wire heated together in a glazed porcelain tube, which was connected with a manometer at one end, and with means for producing a vacuum at the other. It was found that if all gases were first removed from both the ingredients, cementation did not take place unless the iron and the charcoal were in intimate contact. If the ingredients were subjected to mechanical pressure, the amount of cementation increased. The action was, however, so slow that the author concluded that carbon, as such, played but a very small part in the industrial processes of cementation.

—O. R.

White scale on steel; Formation of — and the surface decarbonisation of pipe-annealed steel. C. M. Johnson. *J. Ind. and Eng. Chem.*, 1909, **1**, 459–462.

THE author describes experiments made in an attempt to discover the cause of the coarsely crystalline, white, aluminium-like scale (much lower in carbon content than the remainder of the metal), which is frequently observed on bars of steel which have been annealed in steel pipes, with charcoal, with a view of producing a frosted metallic finish free from scale. Steel having a coating of this white scale does not become hardened file-proof on the outside. Experiments in which pieces of steel were heated in presence of carbon dioxide, hydrogen, charcoal, carbon monoxide, and natural gas in a porcelain tube, and also in the tube containing only air and sealed so that air could be expelled, but no fresh air drawn in, indicated that the most active agent in producing the "bark" (surface decarbonisation) was the rust or black scale adhering to the steel, this being reduced to metal by the carbon of the steel. In a further experiment, a piece of high-carbon steel was heated at 850°–900° C. in the porcelain tube, in which was also placed a porcelain boat containing some hard semi-fused iron oxide. After 18 hours it was found that the hard mass of oxide had been converted into a loose friable substance, whilst the steel showed great surface decarbonisation. After a second heating with a fresh piece of steel, the friable substance in the boat had become light grey in colour and fibrous and was found to contain 98 per cent. of metallic iron. It is suggested that pure metallic iron could be prepared in this way from pure iron oxide by heating it in a closed tube with a sealed vent, in presence of a piece of high-carbon tool steel low in sulphur. The white aluminium-like scale on steel is produced more rapidly at temperatures above 750° C. At a temperature of about 700° C., the surface decarbonisation of steel annealed in a closed tube with a sealed vent is confined to a very thin skin, below which the steel is hardened file-proof. If the steel be polished free from rust and scale, and then annealed in a tube from which all oxygen has been expelled by carbon monoxide, no surface decarbonisation is produced and the steel is hardened file-proof.—A. S.

Iron; Passivity of —. P. Krassa. *Z. Elektrochem.*, 1909, **15**, 490–500.

AN investigation of the potential of iron in strong alkali solutions shows that with 8N–12N solution, maximum activity is reached below the boiling point or after short boiling; with 4N–8N solution longer boiling is necessary, and with still weaker solutions activity is not induced by boiling, though the iron, if once rendered active, remains so in the boiling solution, if stronger than N/1. Iron is best rendered active by boiling in strong alkali solution or by cathodic polarisation. With solutions

weaker than N/1, active iron soon loses its activity. When active iron is anodically polarised, with a weak current, in a solution of alkali at its boiling point, it remains active for a time, but the potential sooner or later begins to change, at first slowly and then rapidly, until finally the value is reached at which oxygen evolved, the iron gradually becoming passive. At the same time, before passivity sets in, the solution becomes coloured bluish-green, owing to the solution of iron and the electrode is coated with a velvety black film of oxide, part of which settles to the bottom of the containing vessel. With a very strong current, even in concentrated solution, evolution of oxygen begins at once without any visible change of the electrode. The author regards passivity as due to the formation of this oxide film, which, under proper conditions, may reach a considerable thickness, though with high current density low alkali concentration, and a low temperature, the thickness is reduced, so that the film may even become invisible. Solution of the film renders the iron active again; strong solutions and a high temperature, therefore, which increase the solubility of the oxide, tend toward activity. It is found that weak solutions, in which iron does not become active at the boiling point, are decomposed by iron at higher temperatures, with the liberation of hydrogen, thus pointing to the activity of the metal. Only ferrous iron is found in the anodic solution, but the film contains also iron in a higher state of oxidation. After cathodic reduction, this film, owing to its extremely fine state of division, is quite active, even in solution, in which massive iron is passive, and, moreover, the capacity of a plate which has been treated in this way is very marked. Potential measurements lead to the view that the active mass of the iron plate in the iron-nickel accumulator is in this form.—F. SODN.

Silver coinage alloys; Changes of structure of — during thermal and mechanical treatment. E. Pannain. *Atti R. Accad. dei Lincei, Roma*, 1909 [5], **18**, **1**, 523–525. *Chem. Zentr.*, 1909, **2**, 239–240.

THE preliminary treatment of the alloy for silver coinage differs from that of the alloy for bronze coins (see this J., 1909, 246) chiefly in that the former, before and after the first series of rollings, is allowed to cool slowly in the air instead of being quenched in water. The alloy contains, on the average, 83.29 per cent. of silver and 16.53 of copper. When the polished pieces of metal are etched with concentrated nitric acid, the structural components, namely large white crystals of a solid solution of copper in silver, surrounded by a dark eutectic, show up distinctly. During the working of the alloy, the structure becomes finer and more uniform. The crystals are deformed by rolling and broken by stamping, whilst heating renders the structure more uniform.—A. S.

Zinc-smelting; Contribution to the chemistry of —. V. Lepiarczyk. *Metallurgie*, 1909, **6**, 409–419.

EXPERIMENTS are described in which pure zinc sulphide was roasted alone, with ferric oxide, with calcium carbonate, and with a mixture of iron sulphide and calcium carbonate in porcelain crucibles of 10 c.c. capacity, by the flame of a Tech burner at a temperature of 850°–950° C. The residue was analysed and the loss in weight determined, the results being tabulated after calculation in percentages of the original amount of substance used. The results show that:—(1). Pure zinc sulphide can be roasted completely to the oxide if the conditions are such that the zinc sulphate produced is again decomposed. (2). Incomplete removal of sulphur is due to incomplete decomposition of the sulphate. Iron oxide influences this by reacting with the zinc sulphide forming ferrous sulphide. Calcium carbonate does not prevent the complete roasting of the zinc sulphide, but forms calcium sulphate. Experiments on reduction, with distillation, were carried out in covered graphite crucibles in a muffle heated to 1300°–1400° C. for fourteen hours, when the crucible was allowed to cool in the closed muffle, and its loss in weight determined, the results being calculated and tabulated as before. It is shown that calcium sulphate and carbon do not quantitatively react according

to the equation, $\text{CaSO}_4 + 4\text{C} = \text{CaS} + 4\text{CO}$. Part of the calcium sulphide produced appears to react with the sulphate according to the equation, $3\text{CaSO}_4 + \text{CaS} = 4\text{CaO} + 4\text{SO}_2$. Zinc sulphide appears to be volatile, since zinc and sulphur are lost in atomic proportions. Iron sulphide is more readily reduced by carbon than zinc sulphide. Ferric oxide, zinc sulphide and carbon yield carbon monoxide and bisulphide, iron sulphide, and the metals iron and zinc, with some reproduced zinc sulphide. In the technical roasting of zinc sulphide ores it is concluded that the iron present in the blende is to a slight extent harmful during the roasting because it prevents the complete oxidation of the zinc sulphide. In the distillation process iron is useful if present as ferric oxide, (1), because during the roasting it converts zinc sulphide into zinc oxide which is then available for reduction; (2), because if calcium sulphate be present, ferric oxide retains the sulphur as iron sulphide, and prevents the zinc forming zinc sulphide. In preparing the mixture for the retort in case the blende contains much calcium, it is advisable to add ferric oxide in order to obtain a better yield of zinc. Of course it is advisable to remove the calcium salts before roasting, preferably by washing; if this were done, the roasted blende would be as easily distilled as a calciferous calamine, since in the absence of calcium sulphate the small amount of ferric oxide usually present in the mineral would be sufficient to convert unroasted zinc sulphide into zinc oxide.—A. H. C.

Lead in solder and in the tin coating of cans for preserved foods; Determination of —. v. Della Croce. Ann. chim. anal., 1909, 14, 245—248.

Solder.—0.5 grm. of the sample is dried in the oven, weighed again, heated with 1.5 c.c. of nitric acid (sp. gr. 1.30) and the mixture evaporated to dryness in a flask. The residue is treated with 2—3 drops of nitric acid and 10 c.c. of water, heated in order to dissolve lead nitrate, and transferred to a 100-c.c. flask. The metastannic acid adhering to the evaporating flask is removed by heating and shaking with about 5 grms. of washed sand and water, the liquid and wash waters being decanted into the graduated flask. The flask is cooled to 15° C., and the contents are made up to 100 c.c., mixed and filtered. Fifty c.c. of the filtrate are transferred to a 100-c.c. flask, and the lead is precipitated with a potassium bichromate solution (of which 1 c.c. precipitates 0.01 grm. of lead), added in portions of 5 c.c. at a time until excess is present. The contents of the flask are made up to 100 c.c., and filtered, 50 c.c. of the filtrate being titrated with a solution of a ferrous salt to determine the excess of bichromate. The lead determination may thus be effected in, at most, an hour and a half. If the solder contains iron, the sample is heated gently (not to boiling) under a reflux tube with 5 c.c. of hydrochloric acid (sp. gr. 1.19) and 3—4 c.c. of water. The solution thus obtained is treated with 100 c.c. of water, and enough ammonia to produce a slight turbidity, and then acidified with hydrochloric acid. The warm solution is precipitated with sulphuretted hydrogen, the precipitate is washed with sulphuretted hydrogen water by decantation, collected and washed. The filter and precipitate are heated and stirred with 5 c.c. of yellow ammonium sulphide, and 10 c.c. of water are then added. The liquid is decanted through a filter, the residue being washed with sulphuretted hydrogen water by decantation and collected. The filter and precipitate are gently heated with 10 c.c. of nitric acid (1:3) until the black precipitate has disappeared, 20 c.c. of water are added, the liquid is decanted through a filter into a 100-c.c. flask, and the residue is washed with warm water until the filtrate is no longer acid. After cooling and making up to volume, 50 c.c. of the filtrate are transferred to a 100-c.c. flask, treated with enough ammonia to produce a faint turbidity, and cleared with a little acetic acid. Precipitation with potassium bichromate is then effected as above described. By deducting the weight of iron (determined in the filtrate from the sulphides) from that of the weight of sample, the weight of solder is found, the lead-content being calculated in the latter (provided that no arsenic, antimony, copper, etc., are present). *Tin coating.*—At least 1 grm. of the coating is removed from the interior of the clean, dry can;

care must be taken not to remove any solder, which often penetrates to the interior of the can; it is impossible to avoid contaminating the sample with iron. The weighed sample is treated with hydrochloric acid as described for solder containing iron, and if the lead-content is high, the further treatment is also the same. Otherwise the hydrochloric acid solution is neutralised with ammonia, and made up to 25 c.c., the lead in solution being determined as sulphate. The filtrate from the lead sulphate is neutralised with ammonia, freed from alcohol by evaporation, made up to 50 c.c., acidified with hydrochloric acid, precipitated with sulphuretted hydrogen, and filtered. The filtrate is used for determining the iron, the weight of the latter being deducted from that of the sample.

—L. E.

Chromium ores; Production of — in the United States. U.S. Geol. Survey, 1908. [T.R.]

THE production of chromic ore in 1908, though showing an increase over any year in the past decade, indicates that American consumers are still very largely dependent upon imported ore, the greater portion of which comes from New Caledonia, Greece, and Canada.

The total production of chromite or chromic ore in the United States in 1908 was 359 long tons, valued at \$5,640. Most of the ore was produced in Shasta County, Cal., but a small quantity came from Converse County, Wyo. Very little domestic ore has yet been used in the manufacture of chromium alloys, potassium bichromate, chrome paints, or other chemical materials.

The imports of 1908 included 27,876 long tons of chrome ore, valued at \$345,960; 216,081 pounds of chromate and bichromate of potash and 3,805 pounds of chromic acid. The total value of all products of chrome ore was \$362,121.

Aluminium; Action of hydrochloric acid gas on —, and quantitative analysis of metallic aluminium. E. Kohn-Abrest. Bull. Soc. Chim., 1909, 5, 768—775.

PURE dry hydrochloric acid has no appreciable action on aluminium in the cold, but at 250°—300° C. the metal is attacked very readily. Any silicon present is completely volatilised at 300° C., and iron is converted into ferric chloride; aluminium oxide, existing in the metal used, remains in the residue unchanged. When a mixture of iron and aluminium, in atomic proportions, is used, the aluminium is first converted into chloride, which is obtained almost pure, and then the iron is attacked, but this is volatilised only in small quantities, ferrous chloride being chiefly produced. The percentage of metallic aluminium present in samples of the metal may be determined by heating about 0.3 grm. to 300° C., first, for about 19 mins., in a current of dry hydrogen, free from oxygen, and then for 25 mins. in a current of dry hydrochloric acid; after cooling in the presence of hydrogen, the residue is weighed, and the chloride in this residue determined volumetrically, so as to obtain the proportion of hydrated oxide in the sample.—F. SODN.

Colloidal silver solution. Traube-Mengarini and Seala. See XX.

PATENTS.

[*Refractory*] *ores; Treatment of —.* A. A. Lockwood, and M. R. A. Samuel, London. Eng. Pat. 6148, March 19, 1908.

COMPLEX lead-zinc ores and the like, which resist separation by mechanical concentrators, are agitated with a solution of sodium or potassium silicate or caustic alkali or both, until the material binding the metallic constituents together is sufficiently acted upon to liberate the particles, after which they are separated by means of mechanical classifiers or the like.—F. R.

Furnaces for obtaining zinc and lead. J. Armstrong, London. Eng. Pat. 13,513, June 25, 1908. Addition to Eng. Pat. 20,543 of 1904.

IN the reduction furnace described in the chief patent (this J., 1905, 1113), the zinc is distilled by heating the ore, mixed with carbonaceous matter, in long narrow

chambers by means of gas-fired flues, which form the walls of the chambers. The present improvement consists essentially in substituting a series of superimposed horizontal heating flues, fired independently, in place of vertical flues, so that the temperature throughout the chamber may be adjusted as required.—F. R.

Zinc: Separation of — from its ores or compounds. H. L. Sulman, London. Eng. Pat. 23,497, June 24, 1908. Addition to Eng. Pat. 701 of 1908 (this J., 1909, 206).

In the process in which zinc is leached out of ores, in the form of zinc bisulphite and precipitated as mono-sulphite, a vacuum or partial vacuum is produced in the furnace in which the mono-sulphite is calcined, in order to accelerate the removal of the sulphur dioxide and water vapour. The furnace may consist of a revolving air-tight cylinder, containing iron balls to break up the charge, and connected with a suitable exhaust pump.—F. R.

Ores: Treatment of —. T. B. Rogerson and P. Donaldson, Glasgow. Eng. Pat. 24,503, Nov. 14, 1908.

Finely divided ores, "purple ore," "blue billy" or the like, are agglomerated into lumps suitable for smelting, by treatment in an inclined furnace, heated by means of one or more tuyères or burners directed into the lower end of the furnace, and supplied with a mixture of blast-furnace gas and the heated air from the hot-blast pipe of a blast-furnace.—F. R.

Desulphurising and agglomerating ores: Process for —. C. Robinson, Mount Vernon, N.Y. U.S. Pat. 926,289, June 29, 1909.

The ore is mixed with fuel and continuously fed, by means of a hopper into a tall narrow chamber. The successive layers of ore pass through a zone of heat which is maintained, without the aid of extraneous heat, by adjusting the supply of air to the narrow chamber.—F. R.

Metals: Extraction of — from ores. W. T. Smith, Los Angeles, Cal. U.S. Pat. 926,718, June 29, 1909.

PULP, consisting of finely divided ore and cyanide solution, is charged into a cylindrical tank, with a conical bottom, having a discharge pipe leading externally from the bottom and discharging into the top of the tank. Superheated steam is injected into the pipe, thereby heating the pulp and causing it to circulate.—F. R.

Basic Bessemer process: Addition of substances containing iron oxide and of lime in the — in order to shorten the after-blow. Eisenhiitten-Akt.-Ver. Düdelingen. Ger. Pat. 210,809, Oct. 8, 1907. Addition to Ger. Pat. 197,591, July 15, 1906.

A PORTION of the material containing iron oxide used in the process described in the main patent (see this J., 1908, 689) is replaced by substances containing manganese oxide. A small portion of the manganese oxide is reduced, but the greater part passes into the slag, rendering the latter more fluid and thus accelerating dephosphorisation of the iron.—A. S.

Slags of lead and copper smelters: Process of recovering oxide of zinc from molten liquid —. W. Witter, Hamburg, Germany. Eng. Pat. 13,964, July 1, 1908. Under Int. Conv., July 2, 1907.

Electrolytes for electrolytic cells. The British Thomson-Houston Co., Ltd., London. From General Electric Co. Schenectady, N.Y., U.S.A. Eng. Pat. 15,792, July 24, 1908.

THE electrolyte consists of a solution of ammonium tetraborate and an organic substance, such as glycerin for use with electrodes one or both of which may consist of aluminium. The cell will thus act as a current valve, or rectifier, or as a static electrical condenser at relatively high voltages, with only a moderate rise of temperature.—B. N.

Electrolytic cells; Aluminium —. The British Thomson-Houston Co., London. From the General Electric Co. Schenectady, New York. Eng. Pat. 1345 of 1909; date of application, Sept. 4, 1908.

In aluminium electrolytic cells, an acid solution of ammonium tartrate is used as the electrolyte, to prevent deterioration of the electrodes when the cells are not in use.—W. C. H.

Electrodes of magnetic oxide of iron: Process for the production of —. Consortium für Elektrochem. Ind., Ges.m.b.H. Ger. Pat. 211,300, Nov. 22, 1907.

METALLIC iron or mixtures of iron and its oxides are burnt in oxygen or in gases rich in oxygen, and the magnetic oxide thus produced is allowed to solidify in moulds of the desired shape. *Example:* A cylindrical hole is bored in a block of magnesite, and one end is closed by a plug of iron or ferrosilicon. A rod of iron heated to incandescence at the lower end is then placed in the hole, and oxygen is blown in through perforations in the walls surrounding the hole. The iron burns, and the molten magnetic oxide produced fills the hole.—A. S.

Electrodes and resistances for electric furnaces, radiators, lamps, and the like. G. Cornaro, Turin, Italy. Eng. Pat. 13,734, June 29, 1908. Under Int. Conv., June 27, 1907.

idisable metals and the like ; Process of and means for preventing — from rusting, after they are electroplated. C. Mason, Kingston-upon-Hull. Eng. Pat. 13,715, June 29, 1908.

IE articles of oxidisable metal, after being suitably epared, are placed in a solution containing copper, tin, zinc, or the latter may be deposited upon them "in a stable state," for the purpose of imparting a preliminary ating. In the case of a zinc coating produced from ie vapour, the deposit is thickened by any suitable lution of tin, zinc, or copper, preferably by a solution of e sulphate and ammonium tartrate in water, the articles ing then dipped in hot water and dried quickly. They e then subjected in an oven or chamber to sufficient heat just melt the metal forming the initial deposit or coat, that "the atoms which form such metal coalesce and ereby render the deposit or coat non-porous." The ticles, after cooling, are prepared to receive a coating of ekel, the latter being deposited from a solution composed nickel sulphate, ammonium tartrate, and water, with without the addition of a small quantity of an organic id, preferably tannic acid.—B. N.

electroplating and like processes. H. and R. S. Hutton, Sheffield. Eng. Pat. 18,246, Aug. 31, 1908.

order to cover those parts most exposed to wear with a icker coating than the remainder, the article to be plated first subjected "to a differential plating by arranging eens or their equivalent (which produce a vignetting ect of the plated material upon said article) between e anode and cathode, and then to an equal or uniform ating." The screens are made of insulating material, th suitable openings opposite or adjacent to the portions the cathode which are to be plated more thickly. The eens may be secured to the cathode, and motion imrted to the same, in order to facilitate the deposition of al.—B. N.

vered glass mirrors [electrolytically] ; Manufacture of —. A. G. Bloxam, London. From E. Hoorickx and A. Hindel, Brussels. Eng. Pat. 2490, Feb. 2, 1909.

E improvements relate to the operation of coating the vered surface of a mirror with a protective layer of per or other suitable metal. A frame, 12, carries the ror, one end of the frame being attached to rollers, 4, apted to roll on an inclined surface, 15, the other end ng supported in hooks, 16, attached to a bar, 7, idly fixed to the frame, 3, carrying the anode. The vement of the frame, 3, in the direction of the arrow,

causes the mirror to descend horizontally in an oblique direction into the electrolyte in the bath, 11, thus avoiding disturbance of the liquid, whilst the complete immersion of the mirror, before the anode enters the liquid, prevents localisation of the current on a small portion of the silvering of the mirror. The current is conducted to the silvered surface by spring clamps, connected with each other and with the negative pole of an electric generator by an insulated flexible conductor. Each clamp consists of two parts hinged together, the lower one having an abutment and an extension adapted to be applied to the edge and underside of the mirror, whilst the upper part has a contact finger adapted to rest on the silvered surface. The flexible conductor consists of a series of short rigid bars forming the current terminals, electrically connected together by lengths of thin flexible conductors, the latter and the ends of each bar being covered with rubber tubing, thus leaving exposed just sufficient of the length of each bar to ensure contact with its corresponding clamp. The two parts of the latter are preferably adapted to turn around the rigid bars, and are pressed against the mirror by an elastic band or spring. A modification of the contact fingers is described, in which the finger makes contact by virtue of its weight, the tip of the finger being rounded for resting upon the frame, in order that the contact portion may adapt itself to the silvered surface. Where the frame, carrying the mirror, forms the cathode, the finger may be made with two conducting surfaces, one making contact with the mirror, and the other resting upon the cathode frame.—B. N.

Ore-reducing apparatus. W. V. Jean, Minneapolis, Minn. U.S. Pat. 926,492, June 29, 1909.

THE apparatus consists of a tank divided concentrically by means of a screen. Anodes and cathodes are suspended respectively in the inner and outer compartments. Agitation is effected by means of a hollow shaft having hollow and perforated radial arms at its lower extremity, which rotates within the inner compartment, air being simultaneously forced into the solution through the perforations in the arms.—F. R.

Ore separating machine ; [Magnetic —]. W. V. Jean, Minneapolis, Minn. U.S. Pat. 926,493, June 29, 1909.

FINELY divided ore and solution are charged into a tank and agitated by means of a hollow rotating shaft having hollow perforated radial arms at its lower extremity, through which air is forced. A magnetic separating element is caused to rotate partly submerged in the solution, and separated by a space from the rotating arms.—F. R.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Cacao butter ; Analysis of —. G. Halphen. Ann. chim. anal., 1909, 14, 254—256.

THE author uses a method for detecting certain vegetable fats and, in particular, "green butter" (*beurre vert*) in cacao butter, depending on the different solubilities of the bromine derivatives. If a solution of "green butter" in twice its volume of carbon tetrachloride is treated with excess of a very concentrated solution of bromine in the same solvent, and, after filtration of the liquid through a mixture of equal parts of sand and starch, 4—5 volumes of petroleum ether are added, it will be found that, on cooling in water at 15° C. for 2 hours, an abundant precipitate is formed. Cacao butter yields no precipitate, and the presence of 10 per cent. of "green butter" in cacao butter is sufficient to produce a precipitate. If only 2—3 volumes of petroleum ether are added to the brominated mixture, 5 per cent. of "green butter" in cacao butter may be detected. To detect "green butter" in chocolates, the fatty matter, extracted in the usual way and freed from solvent, is dissolved in carbon tetrachloride (2 c.c. for each grm. of substance), the solution is heated under a reflux condenser with a little charcoal, cooled and filtered. One c.c. of the clear, colourless filtrate is treated with a solution of bromine (prepared by adding to carbon tetrachloride sufficient

bromine to double its volume), added drop by drop until the red colour persists. The mixture is allowed to react for 1–2 minutes, treated with 3 c.c. of petroleum ether, the tube is hermetically stoppered, and allowed to stand till the next day. Pure cacao butter gives no precipitate, whilst with only 5 per cent. of "green butter," a slight solid deposit is formed. The amount of precipitate increases with the proportion of "green butter" in the mixture.—L. E.

Poppy seed oils ("Huile d'ailette" and "Huile de pavot"). L. Vuathart. *Annales des Falsifications*, 1909, 2, 276–278.

ALTHOUGH poppy seed oil ("huile d'ailette") was defined at the Geneva Congress as "the oil extracted from black poppy seed," the definition is not sufficiently precise. Two kinds of poppy-seed oil are known in commerce, "huile d'ailette" furnished by grey or blue European poppy seeds; and the oil from white or brown, or even blue or black seeds of foreign origin, known as "huile de pavot." "Huile d'ailette" is much more esteemed for culinary purposes and is commercially of greater value than "huile de pavot." Physico-chemical tests do not serve to differentiate the two oils; but the flavour of "ailette oil" is nutty and more fatty than that of "pavot" oil, the latter being somewhat acid. "Ailette" oil, when shaken, shows a persistent froth; "pavot" oil does not. "Huile d'ailette" is of a fine golden yellow colour; "pavot" oil is much paler. The taste and frothing tests are the best to distinguish these two oils.—J. O. B.

*Fish liver oils from *Myliobatis aquila* and *Centrina saliviana**. J. Huwart. *Chem. Rev. Fett.- und Harz-Ind.*, 1908, 200.

*Oil of *Myliobatis aquila* (cagle-ray) liver*.—Sp. gr., 0.9214 at 15° C.; n_D^{20} = 1.4760; acid value, 1.84; ester value, 189.96; Helmer value, 93.6; iodine value, 115.3; acetyl value, 1.4. The separated fatty acids had the m. pt., 34.2° C.; solidifying point, 28.8° C.; acid value, 198.5; saponification value, 203.6; lactones, 5.1 per cent. *Oil of *Centrina saliviana* liver*.—Sp. gr., 0.9058 at 15° C.; n_D^{20} = 1.4751; acid value, 0.5; ester value, 136.3; Helmer value, 99.6; iodine value, 97.7; acetyl value, 13. The fatty acids had the m. pt., 31.2° C.; solidifying point, 24.5; acid value, 131.3; saponification value, 134; lactones, 2.7 per cent.

With strong sulphuric acid *Myliobatis* oil gives first a purple-red, then a reddish-brown and finally a dark brown coloration; *Centrina* oil becomes at first brown, then black. With fuming nitric acid *Myliobatis* oil gives a bright red colour, turning reddish-brown, then somewhat paler; *Centrina* oil shows at first a reddish colour then light yellow and finally light brown. With Beechi's reagent neither oil gives a black precipitate. With Cailliet's reagent applied to the oil in petroleum benzene solution, *Myliobatis* oil gives a bright red to brownish red and, finally, dark brown reaction; *Centrina* oil gives pink, red, reddish brown then dark brown shades.—J. O. B.

Oil and fat analysis; Provisional methods of the American Leather Chemists' Association for —. J. Amer. Leather Chem. Assoc., 1909, 4, 130–138.

DETAILS for the determination of the saponification, acid, and iodine values, unsaponifiable matter, Maumené test, specific gravity, titer-test, melting point, cold test (Millwood), and the cloud-test (Manns), are given as the official methods for the present year.—H. Br.

(B).—RESINS, VARNISHES.

Copaifera paupera; Oleoresin of —. [A new Bolivian *copaiba* "balsam."]. C. Hartwich and A. Jamar. Schweiz. Wech. Chem. Pharm., 1909, 47, 373–380.

THE oleoresin of *Copaifera paupera* is remarkable among the South American *copaiba* "balsams" as being the only kind known to be dextro-rotatory; in this and certain other characters it resembles African *Illurina* *copaiba* "balsam." The oleoresin is light yellowish-brown in colour, and resembles Maracibo balsam in consistence; sp. gr., 0.998 at 15° C.; $[\alpha]_D^{20}$ = +36° in a 100 mm. tube; n_D^{20} = 1.522; direct acid value, 89.7; cold saponification value, 97.25; hot saponification value, 101.5. It gives a positive reaction with the sulphuric and nitric acid test, as if it contained gurjun balsam. It does not contain the crystalline illurinic acid found in African balsam; only a small growth of microscopic hexagonal leaflets could be obtained from the alcoholic solution of the resin acid after 2 months' standing. The bulk of the resin acid is an amorphous, brittle, pale-yellow substance; acid value, 151.06; saponification value, 153.31. Illurinic acid, according to Keto, has the acid value, 177.9; and saponification value, 0. The rotatory power of illurinic acid is $[\alpha]_D^{20}$ = –51.89°; that of the *Copaifera paupera* acid $[\alpha]_D^{20}$ = +41.48°. *Copaifera paupera* "balsam" yielded 22 per cent. of essential oil; sp. gr., 0.916 at 15° C.; n_D^{20} = +18° in 100 mm. tube; n_D^{20} = 1.5048; direct acid value, 1.07; cold saponification value, 1.60. The bulk of the oil distils between 250° and 270° C. at ordinary atmospheric pressure. All its fractions are dextro-rotatory.—J. O. B.

PATENTS.

Gum [resin] and process for extracting same. F. Ephraïm, Santa Barbara, California. Eng. Pat. 17,961, Aug. 26, 1908. Under Int. Conv., Aug. 28, 1907.

THE crushed, dried octilla plant (*Fouquieria*) is suspended in a solvent such as ordinary, or absolute alcohol (either of these alcohols being preferably heated), ordinary alcohol mixed with sodium hydroxide solution, alcohol of almost any kind mixed with ammonia, or acetylene tetrachloride mixed with ammonia. The solution of gum thus obtained, is strained to remove fibre, and may then be used, either

lone or mixed with other ingredients, as a varnish, or it may be evaporated to dryness, a shellac-like gum has been obtained.—L. E.

rosin oil; Process for the preparation of a — from rosin, consisting of a single substance. E. von Boyen. Ger. Pat. 210,830, Jan. 8, 1908.

ORDINARY rosin oil prepared by distillation is a mixture of different substances. It is claimed that by the action of pyrophosphoric acid on rosin at 260°C ., a rosin oil consisting of an individual substance is obtained. The product has a constant boiling point of 350°C ., a high viscosity, and a low acid value. The phosphoric acid can be used over again several times in succession.—A. S.

lastic sealing wax; Process for the preparation of —. H. Bergmeister and F. Schaar. Ger. Pat. 210,965, May 26, 1908.

HELLAC (12.5 parts) is intimately mixed with gutta-percha (100 parts) and a solution of rubber in benzene (25 parts) at 100°C .—A. S.

Chinese wood oil; Process for the conversion of — into a product which gives a smooth, hard, lac-like coating. Chem.-Techn. Laboratorium Meffert. Ger. Pat. 211,405, Sept. 8, 1908.

It is found that Chinese wood oil can be heated above its temperature of polymerisation without solidifying, if care be taken to keep the oil in motion. The product is of the same colour as the original oil; it may be thickened in the same way as linseed oil, and when diluted with turpentine oil or the like, is said to yield varnishes possessing properties similar to those of the best copal varnishes.—A. S.

dipping-varnishes possessing covering power; Process for the preparation of —. H. Zwick. Ger. Pat. 211,520, Feb. 10, 1907.

By adding water and fats or oils to solutions of nitrated cellulose in a mixture of solvents of different volatility and solvent power, or to solutions of mixtures of nitrocellulose with other colloids (resins, balsams), insoluble in water, in one solvent or a mixture of solvents, varnishes are obtained, which possess such good covering power, that satisfactory coatings are obtained by dipping articles in them. Suitable preparations are:—(1). Collodion, 10; ether, 1000; 96 per cent. alcohol, 200; acetone, 10; linseed oil, 40; and water, 75 grms. (2). Collodion, 10; 96 per cent. alcohol, 900; ethyl acetate, 300; cellac, 25; castor oil, 40; and water, 75 grms. (3). Collodion, 100; ethyl acetate, 1000; sandarac resin, 10; and water, 75 grms.—A. S.

(C).—INDIA-RUBBER, &c.

caoutchouc; Notes on the chemistry of —. F. W. Hinrichsen, W. Manasse, K. Meisenburg, and E. Stern. Chem.-Zeit., 1909, 33, 735—736, 756—757.

EDDE'S tetrabromide method (this J., 1907, 1057) gives useful results for the actual caoutchouc present raw or in cold-vulcanised rubber. The method cannot be used if lead or antimony sulphide is present. The milar method of Axelrod (this J., 1907, 1058) for caoutchouc in hot-vulcanised rubber suffers from several defects, the most important being that the mineral filling matter present is weighed as such together with

the tetrabromide, whilst only the weight of its ash is afterwards deducted. This may lead to very serious errors.

To determine mineral filling matters, the authors recommend extraction of the rubber with paraffin oil (b. pt. 230° — 260°C .) or camphor oil (b. pt. 175°C .). One gram of the finely divided sample is heated with 25 c.c. of the solvent in a tared 100 c.c. flask for $\frac{1}{2}$ —2 hours under an air condenser. When the caoutchouc is completely dissolved, the flask is allowed to cool, filled with benzene, and allowed to stand overnight. The solution is then decanted through a Gooch crucible, and the residue repeatedly washed with hot benzene, petroleum ether, alcohol and ether, and weighed. The use of a centrifuge shortens the operation considerably. The values so obtained are within about 2 per cent. of the calculated values. If the sample contains free sulphur it should first be extracted with acetone.

For total sulphur, oxidation by Gasparini's method (this J., 1904, 952; 1908, 340) is recommended. Nitric acid (concentrated or fuming) is electrolysed in a tall 100—150 c.c. beaker between platinum electrodes, the sample being placed in a basket of platinum gauze which forms the anode. With a current of 6—8 volts the oxidation of the sample is complete in $\frac{1}{2}$ —1 hour. If lead compounds and barium sulphate are absent, the solution obtained is evaporated to dryness after adding sodium chloride, the residue is dissolved in dilute hydrochloric acid, and sulphate precipitated as usual. If lead or barium compounds are present, barium nitrate is added before oxidising; the liquid obtained is concentrated, diluted and filtered, the insoluble sulphate being fused as usual.

A number of experiments were made to determine whether a definite amount of sulphur is taken up by caoutchouc, when vulcanised cold with an excess of sulphur chloride. Apparently this is not the case, the combined sulphur in the treated samples varying from 15.5 to 26.15 per cent. Experiments on hot-vulcanising were made by dissolving caoutchouc and sulphur in molten naphthalene and heating in an atmosphere of carbon dioxide. It was found that, when the time of heating was kept constant, the percentage of sulphur taken up varied as the proportion present, and that with the same proportion of sulphur, the percentage taken up varied as the time of heating, at least up to 10 per cent. of sulphur.—A. G. L.

Vulcanised rubber goods; Analysis of —. Frank and Marckwald. Chem.-Zeit., 1909, 33, 812—813.

ACCORDING to Hinrichsen (see preceding abstract) the chief defect of Axelrod's tetrabromide method for the determination of caoutchouc, is that its accuracy is affected by the presence of mineral filling materials. The authors point out that minimum, one of the mineral substances mentioned, is never used in the preparation of good rubber mixings. Moreover, the error due to the presence of mineral filling materials is small compared with that caused by the solubility of the caoutchouc tetrabromide in the solvents employed, a point which appears to have been overlooked hitherto. For the determination of the mineral filling materials, Hinrichsen's proposal to dissolve the rubber in petroleum oil (b. pt. 230° — 260°C .) at the ordinary pressure, is considered to be less satisfactory than the use of xylol under increased pressure (this J., 1908, 989), and Hinrichsen's objections to the use of the autoclave are stated to be quite unfounded.—A. S.

Caoutchouc solutions; Viscosity and coagulation of —. H. W. Woudstra. Z. Chem. Ind. Kolloide, 1909, 5, 31—32.

CAOUTCHOUC, when "dissolved" in toluene or carbon bisulphide, does not pass through parchment paper to the pure solvent on the other side. Solutions of 1 gram in 200 c.c. of toluene, carbon bisulphide, xylene, and carbon tetrachloride filtered through glass-wool or, preferably, paper, become opalescent and finally deposit flocks when kept for some time at 25°C .; at 36°C the clouding is much more rapid, especially in the xylene solution. These reactions agree with the assumption

that caoutchouc is a true colloid. Viscosity determinations on the xylene and toluene solutions showed that the viscosity slowly decreases on keeping the solutions.

—A. G. L.

The guayule rubber industry. J. E. Kirkwood. *Scient. Amer.*, July 10, 1909. [T.R.]

THE guayule (*Parthenium argentatum*) thrives in the dry regions of Northern Mexico and Texas. The plant produces no latex, and the rubber occurs as minute granules distributed throughout the tissues.

R. Endlich (*Tropenpflanzer* IX., 1905) describes several processes for its extraction (see also this J., 1908, 1123). The process of extraction involves the destruction of the plant, and must in time ensure the death of the industry. In 1905 the value of the export from Durango was \$125,478. In 1906, rubber was shipped from Torreon to the value of \$917,571. During the year ending June, 1908, the value exported from the Durango district alone was \$2,250,000.00. Attempts made to cultivate the plant have so far proved a commercial failure. Only about 1 per cent. of the seeds sown reach maturity under the most favourable circumstances. Cuttings fail to grow except from parts of the root, and then only under irrigation, without which subsequent growth is very slow. Unfortunately, plants rapidly grown under irrigation yield no rubber. Without irrigation, it takes twenty years to mature a crop. (See also this J., 1909, 483.)

Caoutchouc and cellulose: Manufacture of a new product from —. Soc. Française de la Viscose, Paris. Eng. Pat. 7302, March 26, 1909. Under Int. Conv., March 28, 1908.

ALTHOUGH a basic solution of cellulose, e.g., in the form of viscose or a solution in cuprammonium, will not mix with the ordinary solutions of caoutchouc, it has been found that such derivatives of cellulose readily amalgamate with the crude rubber latex to give a sufficiently stable and homogeneous mixture for industrial purposes. The two components of the mixture may then be coagulated or precipitated together in intimate association by any of the known means for coagulating and fixing cellulose from its solutions.—J. F. B.

XIV.—TANNING, LEATHER, GLUE, SIZE.

"Tannin"; Suggested terminology for the substances known generally under the name —. E. Perrot and A. Goris. *Bull. Sciences Pharmacol.*, 1909, 16, 189—191. *Chem. Zentr.*, 1909, I, 1998—1999.

For the complex compounds present in the fresh plants, the name "tannoids" is proposed. These tannoids on hydrolysis yield among other products, "tannides" or "tannosides." The tannides possess the properties of the substances usually known as tannins, whilst the tannosides are compounds of the tannides with a carbohydrate. The tannides and tannosides always contain at least one phenolic group; they may yield also a glucoside or alkaloid on hydrolysis. The tannoids may be represented by the general formula $(A-[C_6H_4(O_2)_n-B])$, in which A and B represent chemical compounds combined with the carbohydrate residue. The tannoid of the chestnut tree yields on hydrolysis, the tannide, aesculitannic acid, and dextrose and aesculetin, the products of hydrolysis of the glucoside, aesculin, which is combined with aesculitannic acid in the tannoid. The tannoid of coffee yields caffeine and the tannoside, caffeetannic acid, which in turn can be hydrolysed to caffeic acid and dextrose or mannose. In the tannoid of galls, the compounds, A and B, are identical, the products of hydrolysis being gallic acid and dextrose. The tannoids are easily soluble in water, alcohol, and acetone; slightly soluble or insoluble in ether, petroleum

ether, and chloroform. The enzymes present in the plants decompose them, with production of tannides or tannosic, and may also oxidise the latter to "phlobaphene red" such as "kola red," "cinchona red," etc.—A. S.

Aspergillus niger in tanneries. Bolland and Dr. J. Pharm. Chim., 1909, 29, 573—575.

EXPERIMENTS are recorded on the growth of *Aspergillus niger* in tannery liquors. They were based on Raulin's statement that silver retards or even prevents the growth of this mould. A silver wire network of known weight was fastened to a wooden frame and placed in a vat the surface of a tan liquor of known volume and strength. After a month the *Aspergillus* was present as abundantly in this vat as in neighbouring ones containing the same liquor but no silver. The metal suffered no loss of weight. Raulin's artificial nutrient medium was put into dishes and chestnut extract added to one dish. A known weight of silver wire was added to each dish and the contents were then sown with spores of *Aspergillus*. A fine growth was observed in the dish containing chestnut extract but none on the other dish. Silver wire left for a year in various extracts was not attacked. When experiments were conducted in closed vessels, no *Aspergillus* appeared but in open vessels it grew abundantly. Silver in chestnut extract was not attacked even in presence of nitric acid. Under the same conditions copper and brass were also not attacked, but zinc, iron and mercury were acted upon by the acid. Light rays of different colours did not seem to affect the growth of *Aspergillus*. Liquors protected from the air by oil or petrol were free from attacks of the mould.—H. G. B.

Gelatin-hematin acid method [for tanning liquors]. W. Alsop. *J. Amer. Leather Chem. Assoc.*, 1909, 4, 194—207.

THE gelatin-hematin method (see this J., 1908, 116—1909, 721) of estimating acid in tanning liquors has recently been tested by members of the American Leather Chemists Association and the author gives a report of the work carried out. Several collaborators expressed opinions on the method and these along with tables of results are published in the report. The author considers the agreement between results obtained by different operators and the correctness of the acidity found, to be quite good as would probably be obtained by any of the other methods. He makes no recommendation for or against the adoption of the method, but states that he knows of no other method that would apply equally well to all classes of liquors. It is suggested, however, that a better indicator than hematin is required.—S. H.

Tannin analysis; Official method of the American Leather Chemists Association for —. *J. Amer. Leather Chem. Assoc.*, 1909, 4, 118—124.

THE official method for the analysis of tanning materials for the present year, is given, together with methods of sampling. No alterations are made from that of last year.—H. B.

Leather analysis; Provisional method of the American Leather Chemists Association for —. *J. Amer. Leather Chem. Assoc.*, 1909, 4, 124—130.

A DETAILED account of the official method for the analysis of leather for the present year is given, including determinations of moisture, fat, ash, water-soluble matter and glucose (dextrose).—H. B.

Tanning; Process of —. C. M. Landenberger, London. From J. E. Marwedel, Waywood, N.J., U.S.A. Eng. Pat. 13,768, June 29, 1908.

THE use of tea leaves, tea waste, tea refuse, or an extract of tea is suggested for the tanning of hides. If the tea

reated with lime and then with chloroform or benzene, the former absorbs the aroma and the latter dissolves the caffeine, which two products can be removed by filtration. The dissolved lime can be removed by the addition of a little sulphuric acid which precipitates it as calcium sulphate. The tea material may be used in conjunction with any other tanning material.—H. XV.—MANURES, &c.

Soil samples; Preparation of — for chemical analysis. G. M. MacNider. J. Ind. and Eng. Chem., 1909, 1, 447—449.

THE author gives the results of the analysis of a number of soils of which samples were prepared by passing through sieves of 2 mm. and 0.5 mm. diam. respectively. The results show that in many cases the greater portion of the fertilising constituents is found in the soil particles of less than 0.5 mm. diam., the particles between 0.5 and 1 mm. being composed chiefly of quartz. In other cases the coarser particles contain considerable quantities of elspar, and the analytical results furnished by the two samples of different degrees of fineness differ only slightly. As the author believes, particles of soil of less than 1 mm. diam. fairly represent the soil from which the plant derives nutriment, then analytical results obtained with a sample prepared by passing through a sieve having perforations of less than 2 mm., *e.g.* 0.5 mm., as in the official method of the Assoc. of Official Agric. Chemists (U.S.A.), will be too high and will not fairly represent the composition of the soil. The author recommends passage through a sieve with circular perforations of 1 mm. diam., the portion passing through being termed "fine earth" or "soil," and used for analysis, whilst the residue is classed as "coarse gravel."—A. Carbide [for the manufacture of calcium cyanamide]; Method of grinding —. Cyanid-Ges.m.b.H. Ger. Pat. 211,706, Nov. 25, 1908.

IN the grinding of carbide preparatory to the manufacture of calcium cyanamide therefrom, explosions are liable to occur owing to the formation of an explosive mixture of air and carbide dust. Besides air, carbon dioxide and carbon monoxide also decompose carbide. According to the present patent, the grinding is performed in an enclosed space which is filled with dry nitrogen. In this way not only is all danger of explosions avoided, but any sparks are produced during the grinding, owing to the presence of hard metallic inclusions in the carbide, these only result in the formation of calcium cyanamide from the interaction of the carbide and the nitrogen.—A. S.

XVI.—SUGAR, STARCH, GUM, &c.

Java [Sugar industry]. Internat. Sugar J., 1909, 11, 357—358. [Consular report.]

THE following figures show the production for the past three years:—

—	1906.	1907.	1908.
Planted area acres	260,810	281,750	284,600
Total production tons	1,046,691	1,144,383	1,217,390
Production per acre	4.01	4.06	4.28
Mills working	176	176	177

During the past season, prices and profits have been high. The area planted for the 1909 crop is estimated at 2.8 per cent. more than for 1908. The exports of sugar for the past three years have been as follows:—

Country.	1906.	1907.	1908.
United States	Tons. 192,178	Tons. 309,449	Tons. 456,435
China	127,495	151,187	149,324
Japan	160,709	191,928	135,100
British India	111,527	315,569	303,465
United Kingdom	4,123	12,261	3,453
British Columbia	17,413	12,089	11,558
Australia	39,495	5,726	17,588
Continent of Europe	5,881	20,376	4,557
Other countries	60,906	44,083	24,815
Total	719,727	1,058,668	1,105,095

—L. E.

Sugars; Bacterial flora of Hawaiian —. L. Lewton-Brain and N. Deer. Report of Work of Experiment Station of Hawaiian Sugar Planters' Assoc., Div. Pathol. and Physiol., April 1909, Bull. No. 9, 1—35.

THE authors give detailed descriptions of five organisms isolated from a number of Hawaiian sugars, and describe their action on sugar in liquid cultures and on commercial raw sugars. *Bacillus A.*—Grown on sugar-nutrient agar, the cells average 2 μ in length, whilst on carrots, and in glucose bouillon, the average length is 1.6 μ . The organism does not sporulate, but is very resistant to desiccation, and, hence, is capable of living for an indefinite period in the sugar factory. *Diplobacillus B.*—The cells average about 3 μ in length and 1.7 μ in breadth; the spores are usually terminal, but often central. The organism is very resistant to desiccation. *Bacillus C.*—The cells are about 4 μ long and 1.2 μ broad; the spores are usually central but occasionally terminal. *Bacillus D.*—The cells developed in sugar-nutrient agar are about 3.7 μ long and 1.2 μ broad; the spores are usually central. *Bacillus E.*—The cells average about 3.5 μ in length and 1 μ in breadth, and form spores. Since none of these organisms has flagella, they would be placed in Migula's genus *Bacterium* rather than *Bacillus*. On cultivating the organisms in sucrose-nutrient solutions, it was found that invert sugar is formed more or less rapidly, and that a faculty of rapidly hydrolysing sugar is associated in liquid cultures with the formation of gums; *bacilli A* and *D* form other substances besides invert sugar and gums in sucrose-nutrient solutions. The gum formed by *bacilli A* and *C* was found to have properties identical with those of Greig Smith's levan [levan] (see this J., 1902, 1381), the gum formed by *B. levaniformans*, and the two are probably identical, so that the production of a gum with the properties of levan cannot be held as characteristic of one particular bacterium. With regard to the action on commercial sugars, it was found that *bacilli A* and *C* cause rapid deterioration, whilst *B. D.* and *E.* are less injurious. Deterioration is favoured by high temperature, and by a high moisture-content of the sugar. In conclusion, the authors discuss the precautions to be taken against deterioration of sugar during storage and shipment. The Keen ventilator, whereby a current of air is maintained round the hold of the ship,

but not in it, has been recommended, and in so far as it tends to keep the hold cool, and to prevent the temperature from rising to a point favourable to bacterial action, it should be of great service. The authors suggest that it might be applied to storage warehouses, the latter being built with double walls; the best safeguard against deterioration, however, is the maintenance of the factory in an aseptic condition as possible.—L. E.

Sucroclastic enzymes in Beta vulgaris: Polarimetric study of the —. R. A. Robertson, J. C. Irvine and M. E. Dobson. *Biochem. J.*, 1909, 4, 258—273.

THE most probable explanation of sucrose-formation in the sugar beet appears to be that dextrose and levulose are formed in the leaf region, and are there transformed into sucrose, the latter passing, by means of the leaf meristem, to the root. Assuming that the condensation of dextrose and levulose is an enzymic process, this may be effected by a special enzyme termed the associating enzyme, or it may be due to a reversed invertase action. The authors have investigated the problem of sucrose-formation in the sugar-beet, and to this end, the topography and nature of the enzymes in the plant were first studied. Enzyme preparations were obtained by filtering the aqueous extracts from the leaves, stems, and roots, through several folds of fine muslin, (with more careful filtration, less active preparations are obtained), precipitating the turbid filtrates with alcohol, washing the sludges thus obtained with absolute alcohol, filtering, and washing with dilute alcohol until the washings were optically inactive and ceased to reduce Fehling's solution; the preparations were then examined for the presence of various enzymes. In the case of the roots and stems, the residues left on the muslin filters were also examined. The results of these experiments are given in the following table:—

	Leaf.	Stem.	Root.
Invertase	+	+	0
Diastase	+	+	+
Maltase	+	0	+
Inulase	0	+	+
Emulsin	0	+	+

In the above Table: + = present, and 0 = absent.

Kastle and Clark found that invertase is present in larger quantity than inulase or diastase in inulin- and starch-producing plants such as the artichoke and potato, even in the tubers, when the inulin and starch are being stored (see this J., 1903, 1372). The enzyme, invertase, appropriate for the formation of sucrose, is absent from the beet-root when the sugar is being stored. Since inulin and starch are formed *in loco* in the artichoke and potato respectively, the analogous conclusion in regard to the beet, seems to favour the view that sucrose is not formed *in loco* in the root, but is stored there after translocation as sucrose from the other organs. Various experiments were made with a view to synthesising sucrose from invert sugar by means of reversible zymolysis. Experiments with pure enzyme extracts of beet leaves gave no positive results, but these extracts were found to be free from invertase. With sludge from the stems and from young plants, however, which contained invertase, it was found that a decrease in the levo-rotation of the invert sugar solution occurred, and on subsequent hydrolysis with hydrochloric acid, an increase in the levo-rotation was observed. With the stem sludge the figures obtained indicated that about 4 per cent. of sucrose was formed. With the sludge from the whole of a young plant, the figures indicated that about 6 per cent. of sucrose was formed, thus indicating the greater activity of the plant at the beginning than at the end of the storage period. With regard to the small proportion of disaccharides formed experimentally *in vitro*, the authors point out that the equilibrium stage attained is permanent under these conditions, whilst in the plant the equilibrium phase is only momentary owing to the continual removal of the products as they are formed.

—L. E.

Sugar estates: Statistics of the factory results on a number of Java —. H. C. Prinsen-Geerligs. *Internat. Sugar J.*, 1909, 11, 324—333.

THE author discusses the statistics for the past 10 years of a large number of sugar estates in Java. The attention given to selection and cultivation has caused a considerable increase in the yield of canes, but has had no appreciable effect on the sucrose-content of the cane. This sucrose-content is chiefly determined by climate and soil conditions; a regular and decided increase in the sucrose-content of the cane, in the districts where it is already high, is now improbable. The Black Java or Cheribon cane has been gradually supplanted by the descendants of seedling canes during the last 10 years; two of the most popular varieties of seedling canes happen to possess a high fibre-content, and consequently, the average fibre-content of the cane crushed in Java, and the fuel supply from this source, have risen by about 10 per cent.; many of the newer cane varieties yield bagasse of relatively low juice-content, and this partly compensates for loss of juice due to increased amount of bagasse. The milling work has considerably improved, since in spite of the increase in bagasse, the loss of sucrose in bagasse per 100 parts of canes decreased from 1.36 in 1899 to 1.11 in 1908. Prior to 1903, Java sugar was chiefly delivered as refining crystals, and 5 per cent. of the whole amount as black stroop (obtained by shovelling the last after-product massecuites into mat bags, and allowing the molasses to drain off). Since 1903, the manufacture of white first and second sugars has increased considerably, and in 1908, the sum of these two amounted to 40 per cent. of the total production. The percentage of black stroop has latterly decreased and now amounts to about 3 per cent. Though a much larger amount for loss of sucrose in molasses is recorded when making white sugar than when making refining crystals, the total loss of sugar in molasses and unaccounted for has diminished.—L. E.

Sugar in the beetroot: Determination of —. A. Herzfeld. *Z. Ver. deut. Zuckerind.*, 1909, 627—639.

SOME experiments on the analytical control of the work of a sugar factory, showed that in Steffen's steeping process, the total yield of sugar was apparently about 0.4 per cent. greater than that contained in the raw material. The author has therefore investigated the various methods usually employed in controlling sugar house work, and in the present paper, he describes a modification of the Sachs-Le-Docte method for determining sugar in the beetroot, whereby certain sources of error, inherent in the old method, are avoided. A series of nickel-plated iron beakers (distinguished by consecutive numbers) of the shape and dimensions shown in the figure, and an equal number of weighing dishes, which are unnumbered and all of the same weight, are employed. The beakers are stoppered with corks coated with tinfoil. Twenty-six grams of the sample of pulp are weighed in a dish and transferred to a beaker with exactly 177 c.c. of a mixture of basic lead acetate and water in the proportion of 5 parts of basic lead acetate solution (Ger. Pharmacopoeia) to 100 parts of water; the measured volume of liquid is run in from a special burette. The beaker is now stoppered and thoroughly shaken. If the pulp is very finely divided, the mixture may be filtered at once and polarised. If, however, the pulp is coarse, or if, for any other reason, hot digestion is preferred, the beakers are placed in water heated to 75°—80° C., for 30 minutes, and then cooled; the contents are then filtered and polarised. Sachs has shown that the error introduced by adding 177 c.c. of liquid as above described is practically negligible (see this J., 1906, 1010). The author quotes the results of comparative determinations of sucrose in beetroot pulp by (1), the original Sachs-Le-Docte method of

cold digestion; (2), his own modification of this method, by hot aqueous digestion. In most cases, the results agree, but in a few instances, the modified method gives higher results; the differences are, no doubt, due to incomplete exhaustion of the pulp by the cold method, and the modified method must be considered the more accurate. Results obtained by the modified method were found to agree with those obtained by alcoholic extraction. The author has also modified the extraction method with the view of shortening the time required for its execution. A flask of about 100 c.c. capacity, is filled to one-half with 26 grms. of pulp, alcohol of not more than 90 per cent. strength, and 3—5 c.c. of basic lead acetate solution. The flask is heated under a reflux tube for 10—15 minutes in a water-bath, and the contents of the flask are then introduced into the extraction apparatus. A uniform distribution of the pulp in the extraction apparatus is thus insured. If extraction proceeds too slowly, as sometimes occurs with very fine pulp, an aspirator is provided by means of which the apparatus may be partially evacuated. By means of this modified extraction method, an analysis may be completed in 2—3 hours. This method is particularly suitable for the analysis of exhausted, dried slices and of the so-called "Zuckerschneitzeln" obtained by Steffen's steeping process. Half the normal weight of the finely-ground dry slices are digested in a 100 c.c. flask with 60 per cent. alcohol and 3—5 c.c. of basic lead acetate, until the slices settle to the bottom of the flask; this takes about 20—30 minutes. The flask-contents are then rinsed into the extraction apparatus, the further treatment being as above described. The whole analysis requires, at most, 5—6 hours, whilst with the old method, the sugar is often not completely extracted in several days.

—L. E.

Reducing sugars; Simple method for determination of —. J. Dusehsky. *Dents. Zuckerind.*, 1909, 34, 521—522.

For rapid and convenient use in the refinery, the author has tested several methods for the volumetric determination of the cuprous oxide obtained from reducing sugars. He finds the method of Müller, depending on the oxidation of the cuprous oxide by ferric sulphate, to be as accurate as any other, and to possess the advantage of simplicity.

—J. F. B.

Starch paste; Catalytic changes in —. A. Fernbach and J. Wolff. *Seventh Int. Congr. Appl. Chem.*, London, 1909.

WHEN 5 per cent. starch paste is treated with a few drops of neutral hydrogen peroxide and ammonia and kept at a temperature of 70° to 75° C., rapid liquefaction is observed, the liquid attaining the viscosity of water in about a quarter of an hour. The requisite proportions of the reagents are a quantity of hydrogen peroxide corresponding to 5 mgrms. of oxygen, and about 4 mgrms. of ammonia, per 50 c.c. of paste. The ammonia may be replaced by other alkalis, such as soda, lithia, lime and baryta; but whilst with these, a certain optimum quantity is necessary or the reaction to proceed satisfactorily, an excess of ammonia over the requisite minimum quantity has no retarding influence on the reaction. The optimum quantity in question, under the conditions set forth above, is equivalent to 8 mgrms. of sodium hydroxide. In examining the nature of the alteration produced by ammonia and hydrogen peroxide, the authors have found that the ammonia is partially neutralised, the quantity of substance effecting this result corresponding to 1.6 mgrms. of ammonia per grm. of starch. Similar results were obtained in the case of lime.

The liquefactive action of other substances was also investigated, among them being the sulphates of iron and copper. Numerous experiments were conducted with ferrous sulphate and hydrogen peroxide in different proportions, selected with a view to obtaining complete liquefaction in about 20 minutes. It was found that the weak acidity, due to the ferrous sulphate, was sufficient to retard liquefaction considerably. In one series, in which 2 mgrms. of ferrous sulphate and 10 drops of hydrogen peroxide, containing 7.7 mgrms. of oxygen, were used in 50 c.c. of 5 per cent. starch paste, at a temperature of 70° C., varying quantities of sodium hydroxide were

added; the best result was obtained with 0.8 mgrm., the liquid being very faintly alkaline toward methyl orange, and the viscosity at the end of 15 minutes being 1' 25", as compared with 6' 10" without alkali. On the other hand, the adverse influence of even small quantities of acid was demonstrated by the fact that with 1 mgrm. of sulphuric acid, the viscosity test gave the value 27' 30", whilst even as little as 0.05 mgrm. of acid produced appreciable retardation. Organic acids, especially lactic and succinic acids, were also used. Their effect was only about one-third that of an equimolecular quantity of sulphuric acid; and similarly, ferric sulphate, in presence of the optimum quantity of sodium hydroxide, was only about one-third as active as ferrous sulphate. Copper sulphate, on the other hand, was about twice as effective as the ferrous salt; it was less sensitive to the presence of acids and quite insensitive to the presence of alkali.

Liquefaction was effected by even smaller quantities of hydrogen peroxide, down to a minimum of 2 mgrms. of oxygen, longer time being, however, required.

When ferrous sulphate was used in the reaction with starch under the above conditions, but with an increased proportion of hydrogen peroxide, the transformation produced was not confined to simple liquefaction. It has already been stated that the liquefaction of starch by ammonia is accompanied by the formation of a compound which partially neutralises the ammonia, but which represents only a very small fraction of the starch. With a relatively large proportion of hydrogen peroxide, acting on a small amount of starch, the whole of the starch could be transformed. At the end of two hours at 75°—75° C. the starch ceased to give a colour reaction with iodine, and the liquid had acquired a high reducing power and an acid reaction. Thus, on treating 25 c.c. of starch paste (containing 0.5 mgrm. of starch) with 1 mgrm. of ferrous sulphate, 42 mgrms. of oxygen (as hydrogen peroxide) and 0.6 mgrm. of sodium hydroxide, the quantity of reducing substance, at the moment when a coloration was no longer furnished with iodine, amounted to 0.288 grm. Under the same conditions, hydrogen peroxide alone gave the value 0.071 grm., and a large quantity of starch remained untransformed. The product formed did not appear to be a sugar, since it did not furnish an osazone on treatment with phenylhydrazine acetate.

With regard to the formation of acids, 150 c.c. of 3 per cent. starch paste were treated with 12 mgrms. of ferrous sulphate in presence of hydrogen peroxide corresponding to 190 mgrms. of oxygen. After four hours at 75° C., the acidity corresponded to 40 c.c. of $N/10$ soda, about one-quarter consisting of formic acid. The authors are convinced that the acidity of the liquid is not the cause of the transformation of starch into reducing substance. This latter is nearly insoluble in alcohol, and differs essentially from dextrin by its property of being precipitated, from a concentrated solution, by copper sulphate, like the gums.

Soluble starch. C. Tanret. *Compt. rend.*, 1909, 148, 1775—1776.

THE author prepared soluble starch by a slight modification of Fernbach's method (*Compt. rend.*, 140, 1403), by treating starch for half an hour with cold dilute hydrochloric acid (1:1000), washing well with water, drying at 30° C. until the product contained only 17 per cent. of water, and then heating for 1 hour in a closed vessel at 100°—110° C. The soluble starch thus obtained was extracted with 50 times its weight of boiling dilute alcohol (25°), and the solution filtered whilst hot; the filtrate became turbid on cooling. Half of the starch remained undissolved; on drying and treating with boiling water, about one-fourth of the residue dissolved, the soluble portion having the rotatory power, $[\alpha]_D^{20} = +188.6^\circ$. On treating the weak alcoholic solution with about half its volume of alcohol of 95°, a precipitate was produced which agglomerated on vigorous agitation. This was filtered off, washed with absolute alcohol, and dried first over sulphuric acid, and then at 100° C. The product was only slightly soluble in boiling water; the soluble portion had the rotatory power, $[\alpha]_D^{20} = 208^\circ$ —210°. The

insoluble portion gave an insoluble blue iodine compound, and when dissolved in potassium hydroxide gave a solution which did not gelatinise. It closely resembled the granular amylose of Maquenne and Roux (this J., 1906, 192, 601; 1908, 291, 415). The residue obtained on evaporating the alcoholic solution was dissolved in water, and the solution treated with two successive portions of strong alcohol. The two products thus precipitated had the rotatory powers, $[\alpha]_D^{20}$ 180.5° and 173° and their solutions gave reddish-violet and red colorations respectively with iodine. The residue left on evaporating the filtrate had the rotatory power, $[\alpha]_D^{20}$ 154.5°, gave a red coloration with iodine, and possessed a cupric-reducing power equal to one-third of that of dextrose; this mixture of erythro-dextrins constituted about 8 per cent. of the matter soluble in the boiling dilute alcohol. Soluble starches prepared with hydrochloric acid at a concentration of 4:1000 and varied after-treatments gave similar results, the products being mixtures of substances differing in their rotatory powers, their reducing action on Fehling's solution, the colorations produced by them with iodine, and their solubility in alcohol of various concentrations. The author suggests the name "solubilised starch" for such products.—A. S.

Yeast: Nuclein ferments of —, M. N. Straughn and W. Jones. J. Biol. Chem., 1909, 6, 245—255.

THE authors show that yeast does not contain xanthoxydase—a ferment which converts hypoxanthine into xanthine and the latter into uric acid—in the following way:—Compressed yeast (300 grms.), distilled water (1 litre), and chloroform (6 c.c.) were kept in a closed vessel for 15 hours at the room-temperature, with frequent and violent agitation, the insoluble matter then being removed by centrifuging. A quantity of the extract (750 c.c.) was treated with hypoxanthine (400 mgrms.) dissolved by suspending in warm water and adding just enough sodium hydroxide to effect solution. The whole was kept at 38° C. for 4 days, a slow stream of air from a wash-bottle containing chloroform being passed through the liquid for about half the time. A drop of acetic acid was then added, and the liquid was heated to boiling and filtered. The filtrate was treated with 19 c.c. of dilute sulphuric acid, evaporated to about 150 c.c., boiled for half an hour to decompose any trace of protein, and examined for xanthine bases. Small quantities of xanthine and adenine (evidently from the nucleic acid of the yeast extract), but no guanine nor uric acid were found; a quantity of hypoxanthine was recovered equivalent to 90 per cent. of that added. These results show that the yeast does not contain xanthoxydase. The function of guanase is to convert guanine into xanthine; the authors show that yeast (extract) is capable of transforming relatively large quantities of guanine into xanthine, i.e., that yeast contains guanase. They also show that the yeast contains no adenase—a ferment which converts adenine into hypoxanthine—since the extract does not attack the small amount of adenine formed from its own nucleic acid. In their experiments on yeast digestions, the authors have repeatedly observed the occurrence of hypoxanthine in very small quantities, and are convinced that its presence is due neither to adenase nor to decomposition of adenine by the methods of isolation employed.—L. E.

Fermentation: Formation of succinic acid in alcoholic —, F. Ehrlich. Z. Ver. deutsch. Zuckerind., 1909, 645—672.

THE author has previously shown that the higher alcohols which occur in fusel oil, are formed by the fermentation of amino-acids by the yeast (see this J., 1905, 683; 1907, 28, 480). Various observations appear to show that suc-

cinic acid is formed in an analogous way. In view of the similarity of constitution, it seemed probable that aspartic acid is the material from which succinic acid is formed, but neither this view, nor the author's previous suggestion, that aspartic and glutaminic acids yield ethyl and propyl alcohols respectively, proves to be correct. Further experiments showed, that whilst addition of aspartic acid to a fermenting sugar solution causes a decrease instead of an increase in the yield of succinic acid, addition of glutaminic acid causes a large increase in the yield. Hence the succinic acid formed during fermentation with yeast is derived from glutaminic acid. The author now shows that the formation of succinic acid is quite analogous to that of fusel oil. In a series of fermentation experiments, in which pure sugar solutions were fermented with various quantities of pure yeast cultures (different races of yeast, different samples of the same race, and samples of the same race identical except in respect of age were used), amounts of succinic acid, ranging from 0.24 to 0.60 grm. per 100 grms. of sugar fermented, were obtained. The formation of succinic acid under these conditions is easily explained; owing to want of the most essential nutriment, part of the yeast dies. The contents of the dead cells pass into the solution and nourish the still living cells. In this process, autolysis of yeast protein must occur, and glutaminic acid is one of the amino-acids formed in this autolysis (compare Schenck, this J., 1905, 555). The still living yeast decomposes these amino-acids and utilises the ammonia set free for protein-synthesis; the residual complex, after further alteration (oxidation or reduction) leaves the yeast cell as a product of metabolism. In this way succinic acid is formed during the fermentation of pure sugar with a pure yeast culture. That the amount of succinic acid obtained in the above-mentioned experiments, varied considerably, is to be ascribed to the use of yeasts of different compositions; in three experiments, in which samples of yeast identical in every respect, were used, the yields of succinic acid were nearly equal. That the yield of succinic acid is proportional to the alcoholic fermentation of the sugar, accords with the author's theory, since protein-decomposition of the yeast only proceeds normally in presence of sugar; moreover, with complete fermentation of equal weights of sugar by different quantities of the same yeast, the amounts of succinic acid formed are nearly equal. Besides aspartic acid, addition of other amino-acids, and of ammonium salts, to fermenting sugar solutions, causes a decrease in the yield of succinic acid, from which it must be concluded that the nitrogenous nutriment protects the yeast protein from decomposition. If a comparatively small quantity of glutaminic acid is added to a fermenting sugar solution, the yield of succinic acid is greater than that theoretically obtainable from the added glutaminic acid; it appears that the yeast first decomposes the added acid, and is then driven by nitrogen-hunger to attack its own protein. The author has also found that presence of sugar is necessary to the formation of succinic acid. He concludes from this, and other results, that the carbon complexes required in synthesising yeast protein, are derived from the fermenting sugar and that perhaps the only purpose of alcoholic fermentation in general, is to supply the energy and carbon material for synthesising the yeast protein. Further experiments showed that acetone permanent yeast cannot convert glutaminic into succinic acid. The author has previously suggested that the mechanism of the formation of amyl alcohol from leucine may comprise conversion of the leucine into leucic acid, which then decomposes into valeric aldehyde and formic acid, the bulk of the valeric aldehyde being converted by reducing enzymes to amyl alcohol, whilst a small part is oxidised by oxydases to valeric acid. He now suggests that glutaminic acid may be decomposed in an analogous way: according to this scheme, the first decomposition-product is hydroxyglutaric acid which decomposes into formic acid and the half-aldehyde of succinic acid, the latter being quantitatively converted into succinic acid by the action of yeast oxydases and atmospheric oxygen. Since fusel oil and succinic acid are not decomposition-products of sugar fermentation itself, and since it is doubtful if the formation of lactic acid and volatile acids in fermentation, is traceable to the sugar (compare Sator,

this J., 1907, 217), only glycerol, besides carbon dioxide and alcohol, is left for consideration as a fermentation product of sugar. Though Buchner and Meisenheimer have shown that glycerol is formed in fermentation with cell-juice (see this J., 1906, 998), the author considers it possible that this compound is derived, not from the sugar, but perhaps from yeast nucleic substances which are present in yeast juice in appreciable amount. If such is the case, the old equation of Gay-Lussac,

would be rehabilitated.—L. E.

XXVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Benzoic acid; Detection of — in meat and fats. K. Fischer and O. Gruenert. Z. Untersuch. Nahr. Genussm., 1909, 17, 721—734.

THE following method of extracting benzoic acid from flesh products was found the most suitable:—50 grms. of the finely divided material are mixed with 100 c.c. of 50 per cent. alcohol, and the mixture acidified with dilute sulphuric acid and allowed to stand for 30 minutes, with frequent stirring. It is next pressed in muslin, and the expressed liquid rendered alkaline and heated on the water-bath until all alcohol has been expelled. When the volume has been reduced to about 50 c.c. the liquid is mixed with 5 grms. of sodium chloride, acidified with dilute sulphuric acid, and heated to the boiling point. It is then cooled and filtered, the filtrate shaken out with ether, and the ethereal extract washed with water and evaporated at a low temperature. About 50 to 60 per cent. of the benzoic acid present was thus extracted, whereas the yields were considerably less by the other methods commonly employed. This residue was used in comparative tests for the detection of benzoic acid by different methods. For the iron chloride test it was dissolved in water containing ammonia, and the solution evaporated to 1 c.c. and treated with one drop of a 1 per cent. solution of ferric chloride. The presence of 0.02 per cent. of benzoic acid could thus be detected both in fresh and smoked flesh. In the case of fats, as little as 0.01 per cent. of benzoic acid could be detected. Brevan's test (formation of "aniline blue"

on adding to benzoic acid a solution of rosaniline hydrochloride in aniline) failed completely in the case of meats and fats. Röhrig's reaction (conversion of benzoic acid into its ethyl ester, recognisable by its odour) was capable of detecting 0.02 per cent. of benzoic acid in fresh meat, and 0.01 per cent. in fats, but failed when applied to smoked flesh. The similar test depending on the conversion of the benzoic acid into benzaldehyde enabled 0.04 per cent. of benzoic acid to be detected in fresh meat, but failed with smoked flesh. In the case of lard, 0.01 per cent. could thus be detected, but 0.05 per cent. could only occasionally be found in margarine and never in butter. The salicylic acid test was most sensitive when carried out as follows:—The residue was dissolved in a few drops of sodium hydroxide solution and about 1 c.c. of water, and evaporated to dryness in a silver crucible on the water-bath, and the residue fused with about 2 grms. of coarsely powdered potassium hydroxide. After 2 minutes the mass was dissolved in water, and the solution acidified with sulphuric acid, and extracted with ether. The ethereal extract was washed three times with water, and the ether evaporated (after the addition of 1 c.c. of water) at a low temperature. The aqueous residue, filtered if necessary, was then tested with a few drops of a freshly prepared 0.05 per cent. solution of ferric chloride. In this way 0.01 per cent. of benzoic acid could be detected in fresh flesh, 0.02 per cent. in smoked flesh, and 0.005 to 0.01 per cent. in lard, margarine and butter.—C. A. M.

Extract of meat; Constituents of — R. Engeland. Ber., 1909, 42, 2457—2462.

THE author prepared a quantity of carnine from extract of meat, and purified it by means of the double gold chloride of the base. The chloride of carnine was dissolved in ethyl alcohol containing hydrogen chloride. After heating and evaporating, the residue was treated with platinum chloride, when the platinum chloride compound of carnine ethyl ester was produced. This substance has the same properties and composition as the platinum chloride compound of novaine ethyl ester, and the author considers it highly probable that these two substances are identical. The platinum compound of carnine ethyl ester was treated with acetyl chloride, when acetyl-carnine was produced. The platinum compound of this substance, $(C_8H_{14}O_4N)_2PtCl_6$, melts at 199° C., and decomposes at 201° C. When carnine chloride is oxidised with calcium permanganate, β -homobetaine is produced. The author considers that carnine can be regarded as α -hydroxy- γ -trimethylaminobutyric acid.—F. SUDN.

Nitrates [in water]; Determination of small quantities of — L. Farcy. Bull. Soc. Chim., 1909, 5, 775—779.

A COMPARISON of the method of Granval and Lajoux for the determination of nitrates in water (this J., 1909, 740) with those of MacGowan (J. Chem. Soc., Trans. 1891, 59, 530) and Frerich (this J. 1903, 1209) shows that the first, as modified by the author (*loc. cit.*), is to be preferred in the presence of chlorides and ammonium salts the latter causing quite erroneous results to be obtained by the other methods.—F. SEDN.

Waters; New method for the hygienic control of — Spitta and Pleissner. Arch. Kais. Gesundh.-Amt., 1909, 30, 463—482. Chem. Zentr., 1909, 2, 61—62.

AN apparatus (see following abstract), which registers continuously and automatically variations of electrical

conductivity, has been constructed, and used for controlling a river water receiving waste liquors from the manufacture of potassium chloride. The record thus obtained gives indication of undue contamination of the water, extent of such contamination, and the time at which the contamination occurred. The method was found capable of detecting the addition of 1 part of the waste liquor to 200 parts of Spree water, and has the advantage that it allows of the detection of sudden transient alterations of the character of the water, which would probably not be discovered by the ordinary methods of chemical and bacteriological control. It would prove especially serviceable for indicating when a chemical examination of the water was desirable. Further in places where water purification by means of ozone is carried on, it would afford useful information with respect to the amount of ozone needed at different periods.—A. S.

Electrical conductivity of waters; Measurement and registration of the —, using a direct current. M. Pleissner. *Arch. Kais. Gesundheits-Amt.*, 1909, 30, 483–522. *Chem. Zentr.*, 1909, 2, 62–63.

AN apparatus is described which allows of the automatic and continuous registration of variations of the electrical conductivity of a water. A current of known and approximately constant voltage from a battery of six lead accumulators (average total E.M.F. 12.5 volts; capacity 27 ampere-hours), is sent alternately through a wire resistance of 200 ohms, and through the water by means of two graphite electrodes suspended from a float of paraffined cork. The direction of the current is reversed every two minutes. The current strength in the two different circuits is measured by means of a modified recording milliamperè-meter for direct current. The results are recorded in the form of two curves of which one represents the strength of the current passing through the water, whilst by the other the E.M.F. of the battery can be controlled. The specific conductivity is calculated by

means of the equation: $x = \frac{iC}{k - p - i}$; where i is the current strength recorded, k is the E.M.F. of the battery, p is the polarisation, and C the resistance-capacity of the pair of electrodes. The polarisation for a given current-strength can be obtained from a curve derived empirically; in the case of most natural waters, the values correspond for the most part with those found for magnesium chloride solution. It is stated that even in the most unfavourable cases the specific conductivity of natural waters can be determined with an error of less than 5 per cent. The values for the specific conductivity are calculated for a normal temperature of 18° C.: for the waters of the Rivers Rhine, Spree, Mosel, Unstrut, and Oder, the temperature-coefficients of conductivity were all approximately 0.023.—A. S.

Determining nitrate- and nitrite-nitrogen. Zeller. See XXIII.

PATENTS.

Refuse; Disposal of house — [as fuel, paving slabs, etc.]. A. D. Furse, London. Eng. Pat. 23,765, Nov. 6, 1908.

UNSORTED house refuse is ground to a uniform powder in a suitable disintegrator, and then mixed, in a dry state, with a certain proportion of binding material, such as solidified pitch, preferably possessing deodorising, disinfecting, and calorific properties. The mixture is agglomerated by means of heat, and then, by pressing into moulds of various sizes, it is converted into fuel briquettes or "nuts," or into paving blocks or slabs. In making paving blocks or slabs, hardening materials such as a silicate, pulverised flint, or granite, cement, slag, etc., may be added.—L. E.

Ozone; Apparatus for sterilising water with —. Felten und Guillaume-Lahmeyerwerke Act.-Ges., Frankfurt on Maine, Germany. Eng. Pat. 6013, Mar. 12, 1909. Under Int. Conv., Aug. 31, 1908.

IN a system for sterilising domestic water by means of ozone, the ozone generator is automatically switched in

whenever the water tap is opened, and ozonised air is drawn from the generator by the action of the waste itself. According to this invention a single generator is caused to serve several taps by carrying narrow supply pipes for ozonised air from a central generator separately to each of the taps. Each tap is provided with a suction and mixing nozzle, by means of which the escaping water is efficiently sterilised by the ozone drawn through. In order to prevent the access of atmospheric air through the taps, when water is drawn from one tap, each tap is provided with a check-valve so that only ozonised air can be drawn in.—J. F. B.

Filtering apparatus [for water purification]. H. Leister. Ger. Pat. 211,064, Jan. 23, 1908.

THE apparatus is of the type in which several filtering layers are arranged one above the other, with intervening spaces, in a casing, each filtering layer being connected to special inlet and outlet compartments, which communicate with common outflow and wash-water supply pipes respectively. It is intended specially for the purification of water by means of permutites or artificial zeolites (see this J., 1907, 711, 1251; also Ger. Pat. 197,111, this J., 1908, 587). One of the filtering layers is of the usual kind for the removal of mechanical impurities, whilst the others are composed of permutite. The wash-water supply pipe which is common to the mechanical and chemical (permutite) filtering layers, is provided with a branch pipe, through which a regenerating liquid is supplied to the permutite layers, suitable cocks being provided so that this liquid does not pass through the mechanical filter. Thus, when the filter needs renewing, first the regenerating liquid is passed through the permutite filters, and then wash-water is passed through both mechanical and chemical filters, in both cases in the opposite direction to that followed by the water under treatment.—A. S.

XIX.—PAPER, PASTEBOARD, &c.

Castor oil plant; Paper pulp from the —. Walle. Papier Markt; through Paper Making, 1909, 28, 279.

THE writer has succeeded in establishing a large variety of the castor oil plant named *Ricinus giganteus*. The plant grows in Italy to the height of 20 ft. in a single year, its circumference at the base being 12–14 ins. The stem thickens considerably in subsequent years, and may measure 30 ins. round by the end of the third year. This stem yields 50 per cent. of papermaking cellulose fibres of a quality similar to that of poplar, but finer and more easily bleached. A *Ricinus* is said to yield after 2 years' growth as much cellulose as a poplar of 8–10 years' growth, and to require a lower proportion of chemicals for its isolation. The *Ricinus* requires a warm and moist climate, free from frost, and 2-year old plants might be grown in Southern Italy. 1-year old plants might be cultivated further north. The plants would be grown primarily for seed, and the stem would then be cut into lengths, barked and digested in the same way as poplar wood. To supply 20 tons of cellulose daily, it would be necessary to plant 250 acres with 2,000,000 plants, each yielding 13–22 lb. of wood. The value of the wood at the pulp mill is estimated at 1s. 6d. per cwt., and its cost of cultivation, with a biennial harvest, at 8s. 9d. per ton.—J. F. B.

Chromates as colouring matters for paper. E. W. L. Skark. Papierfabrikant., 1909, 7, 647–654.

LEAD chromate is frequently employed as a yellow or

orange colouring matter for paper pulp, being generally precipitated *in situ* by double decomposition between lead acetate or nitrate and potassium bichromate. If lead nitrate be used, the nitric acid produced by the action of the bichromate tends to dissolve some of the lead chromate; the bichromate should therefore be converted into the normal chromate by the addition of alkali before use. This complication does not arise when lead acetate is employed. The shade of the precipitate is very variable and depends not only on the composition of the product, but also on the temperature at which it is formed. The fine precipitate of lead chromate coagulates on heating, and this shrinkage in volume causes a darkening of its shade. For chrome yellow shades, 2.5 parts of lead acetate require 1 part of potassium bichromate. An excess of lead salt gives a precipitate with a fiery, dark lemon yellow shade. If, on the other hand, pale lemon to sulphur yellow shades be desired, a portion of the lead must be precipitated in the form of sulphate, by substituting for some of the bichromate an equivalent quantity of sulphuric acid, or preferably sodium sulphate. The composition of the water has an important influence on the shade, chalky waters tending to produce basic lead acetate and an orange tone. Alum only changes the shade of chrome yellow when it is added before the reaction is complete, or when an excess of lead salt over bichromate is present. If normal lead chromate be treated with sodium hydroxide or hot milk of lime, it is converted into chrome red, a basic lead chromate of variable composition, but generally approximating to Pb_2CrO_4 . The maximum red coloration is obtained by the interaction of 1 mol. of lead acetate, 1 mol. of potassium bichromate, and 4 mols. of sodium hydroxide. If the mixture be heated, the same colour may be obtained with only half the quantity of alkali, but the precipitate shrinks considerably in volume. Since chrome red always contains free lead oxide, it is not stable in presence of alum and cannot be used for colouring sized papers. Chrome orange is a mixture of chrome yellow and chrome red obtained by limiting the proportion of alkali. In colouring with chrome yellow, the lead salt is added first; it is better to under-dye than to colour too heavily in the beater. Since the reaction takes place instantaneously, any deficiency of colour may be made up in the stuff-chest; but if too much colour be added it cannot be conveniently reduced by the subsequent admixture of white pulp, because the paper will not be uniformly coloured. The lead chromate shows a tendency to become basic, not only by heating, but also on long standing in the chest; constancy of shade is, therefore, only obtained by steady working. A good test for the presence of chromates in paper consists in moistening the paper with a drop of sodium hydroxide and applying a drop of an acid solution of silver nitrate to the edge of the spot. A red streak of silver chromate will be formed at the junction of the two liquids. The analysis of the colouring matter in the paper consists of determinations of the chromium, lead and lead sulphate, which may be effected either on the ash or on the paper by decoction. Lead sulphate is extracted by boiling with sodium thiosulphate; chromates may be determined volumetrically with standard arsenite in a decoction made with sodium hydroxide.—J. F. B.

Paper; Penetration of gum solution in gumming — W. Herzberg. Mitt. kgl. Materialprüfungsamt Gross-Lichterfelde West, 1909, 27, 133—135.

It has been found that if certain kinds of paper are first ruled on one side, and then gummed on the other, the gum solution will penetrate through the paper, and cause unsightly blotches on the printed side, especially in the vicinity of the printing. The cause of this appears to be injury to or removal of the size of the paper by some constituent of the printing ink used. As a remedy it is suggested that the paper be first gummed, and then ruled; this may not always be feasible, but is even now done occasionally. Further that more strongly sized paper be used, and if the gum penetrates the paper even then, that a stronger solution of gum be employed.

—A. G. L.

PATENTS.

Bamboo pulp and other similar materials; Treatment of — J. S. Turner and A. W. Maxwell, London. Eng. Pat. 6277, March 20, 1908.

THE pulp prepared by the digestion of matured bamboo has a brown colour not readily removed by the ordinary bleaching agents. Bamboo half-stuff is treated with electrolytic "chlorine," that is, electrolysed brine and acid. Chlorinated products are removed by digestion with alkali, and the final cellulose bleach is effected by usual methods.—J. F. B.

Turpentine oil recovered in the manufacture of sulphate-cellulose; Process for improving the odour of the — C. G. Schwalbe. Ger Pat. 210,829, April 25, 1908.

A CURRENT of oxides of nitrogen is led through the crude oil in order to oxidise the mercaptans, etc., and the oil is then further purified with sulphuric acid and caustic soda in the usual way. (Compare this J., 1909, 37.)—A. S.

Cellulosic films; Treatment and application of — J. E. Brandenberger, Thion-les-Vosges, France. Eng. Pat. 24,809, Nov. 18, 1908.

FILMS of cellulose, obtained preferably from the xanthogenate, are embossed or decorated in various ways. The films themselves, in the course of their formation, may be made transparent, opaque, coloured, metallised, etc. The finished films may be printed or embossed in decorative designs, and the embossed reliefs may be padded with appropriate composition (mastic), with or without an external support. Or the supports themselves may be decorated, and the dry or moist films attached by means of adhesives, and the product embossed, its hollows being filled with a plastic or rigid material to which a second support is then applied. Suitable supports are paper, cardboard, textiles, leather, wood, foliated metals, etc.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Conium alkaloids; Isolation of the — from animal tissues and the action of living cells and decomposing organs on these alkaloids. W. J. Dilling. Biochem. J., 1909, 4, 286—299.

THE author has investigated various methods for the isolation of coniine, conhydrine, and pseudo-conhydrine from urine, blood, and various animal tissues previously treated with small quantities of these alkaloids, and has also studied the action of living and of decomposing tissues on the alkaloids. The best method for isolating coniine from animal tissues is that of distillation (with sodium carbonate). Of 10 mgrms. of coniine salt added to 200 c.c. of urine or to 100 grms. of horse's liver or spleen, from 41.6 to 83 per cent. was recovered by this method. This alkaloid appears to be decomposed both by living cells and by decomposing tissues. Conhydrine and pseudo-conhydrine can be isolated from animal tissues in appreciable amount by extraction with alcohol and ether and by precipitation with phosphotungstic acid, but the results are not sufficiently constant to allow of any definite conclusions as to the action of living cells or decomposing tissues on these poisons.—L. E.

Lead number of vanilla extracts. H. L. Jackson and W. T. McGeorge. J. Ind. and Eng. Chem., 1909, 1, 478—479.

EXTRACTS were prepared in the laboratory from different varieties of vanilla beans by a method of very slow percolation with alcohol of different strengths. It was found that for extracts prepared from equal weights of a given kind of beans, the lead number (see Winton, this J., 1906, 957) was practically constant, regardless of the concen-

tration (between 20 and 65 per cent.) of the alcohol used in the percolation. Tests with three extracts, of which 100 c.c. corresponded to 5, 10, and 15 grms. respectively of vanilla beans, indicated that the lead number of the extract is a measure of the quantity of beans used, when this does not exceed 10 grms. per 100 c.c.—A. S.

Curcuma (turmeric) oil. H. Rupe, E. Luksch, and A. Steinbach. Ber., 1909, 42, 2515–2520. (See this J., 1908, 90).

The oil examined had the sp. gr. 0.9388 at 20° C., and $[\alpha]_D^{20} = -24.76^\circ$ at 20° C. On distilling 100 grms. at 10–5 mm., 1.6 grms. boiled between 80° and 117° C., and was found to contain *n*, (*a*), phellandrene. The principal fraction (82 grms.) boiled between 146° and 160° C. at 10 mm. On further fractionation this portion boiled at 155° to 158° C. at 11 mm. and was found to be identical with the turmerol of Jackson and Menke (Amer. Chem. J., 1882, 4, 77, 368). It yielded no crystalline derivatives. When curcuma oil is boiled with alcoholic potassium hydroxide, a ketone, *curcumanone*, $C_{15}H_{14}O$, is produced. When pure, curcumanone boils at 122° C. at 11 mm. It is a colourless mobile oil, with a sharp ginger-like smell. The sp. gr. is 0.9566 at 20° C., and it has $[\alpha]_D^{20} = -80.55^\circ$ at 20° C. The semicarbazone melts at 120°–121° C. It condenses with benzaldehyde to form benzylidene-curcumanone, $C_{15}H_{14}O : CH.C_6H_5$, melting at 106° C. The piperonal compound, $C_{15}H_{14}O_3$, melts at 86° C., and the anisaldehyde compound at 77°–78° C.—F. SUDN.

Iso-pinene: Constitution of —. O. Aschan. Översigt af Finska Vetenskaps-Soc. Förhandlingar, 1908, 51, 1–17. Mfd. A. No. 9. Chem. Zentr., 1909, 2, 26–27.

The author has previously shown (this J., 1907, 776) that the liquid "first runnings" from the crude camphene formed by the action of bases on crude pinene hydrochloride contains a hydrocarbon, pinolene ($C_{10}H_{16}$), boiling at 145°–146° C. This yields with hydrochloric acid an addition-compound, which when treated with aniline gives the isomeric hydrocarbon, isopinene, boiling at about 10° higher than pinolene. Isopinene hydrochloride, m. pt. 36°–37° C., is identical with the addition compound of pinolene and hydrochloric acid. It has now been found that pinolene consists of a mixture of two hydrocarbons, α - and β -pinolene, which can be separated by means of permanganate solution at 60°–80° C., the former being oxidised to *r*-camphoric acid, whilst the latter remains unattacked. Pure β -pinolene boils at 142°–144° C., has $[\alpha]_D^{20} = +0.28^\circ$, sp. gr. 0.8588 at 20° C., and $n_D^{20} = 1.44769$; its molecular refraction, 42.37, indicates that it is a triyclic compound containing a trimethylene ring. When its ethereal solution is saturated with dry hydrogen chloride at 15° C., it yields a volatile hydrochloride, m. pt. 25°–26° C., which when treated with aniline yields pure isopinene. The latter hydrocarbon boils at 154.5°–155.5° C., and has the sp. gr. 0.8658 at 20°/4° C., $n_D^{20} = +2.61^\circ$, $n_D^{20} = 1.470253$; its molecular refraction indicates that it is a bicyclic compound with one ethylenic linkage. By oxidation with permanganate two acids were obtained from isopinene: one which the author names *fenchonic acid*, $C_{10}H_{16}O_3$, m. pt. 126°–128° C., was a ketone acid and yielded apocamphoric acid on treatment with bromine and alkali; the other was *cis-apocamphoric acid*,

m. pt. 200° C. The author concludes that isopinene has the constitution ascribed by Wallach to fenchene. In view of the conflicting views as to the constitution of fenchene, the author considers that more rational names are needed for the hydrocarbons *d*-l-fenchene and isopinene, and he proposes a nomenclature based on the formula,

for norcamphane. According to this plan, *d*-l-fenchene would be metho-2-dimethyl-7,7-norcamphane, and isopinene, trimethyl-2,7,7-norcamphene-2.—A. S.

Neuralteine, pyramidon, and antipyrine: Reactions for distinguishing —. A. Monferrino. Giorn. Farm. Chim., 1909, 58, 145–151. Chem. Zentr., 1909, 1, 2029.

Neuralteine (sodium salt of sulphomethylphenetidine).—If a few drops of a solution of neuralteine, which has been coloured violet by addition of ferric chloride, be added to concentrated sulphuric acid, a green coloration is formed which changes to blue on adding a larger quantity of the solution. Addition of ferric chloride to an alcoholic solution of the substance produces a reddish colour, changing to chestnut-brown and green; the colour becomes brighter on addition of sulphuric acid. A 1 per cent. aqueous solution is coloured reddish-yellow by addition of concentrated sulphuric acid and nitric acid. Stannous chloride produces a white precipitate in the aqueous solution. A solution of 1 part of neuralteine in 100,000 is coloured reddish-yellow by addition of 1 drop of potassium nitrite solution (1:20) and 1 drop of concentrated sulphuric acid or glacial acetic acid.

Pyramidon (dimethylaminoantipyrine).—A few drops of the solution coloured violet by ferric chloride produce a faint blue coloration when added to concentrated sulphuric acid. The sensitiveness of the reaction with potassium nitrite is 1:1000 in presence of sulphuric acid and 1:10,000 in presence of glacial acetic acid. *Antipyrine (phenyldimethylpyrazolone).*—The solution coloured red by ferric chloride gives a chrome-yellow coloration when added to concentrated sulphuric acid. The reaction with potassium nitrite does not take place in presence of glacial acetic acid, and in presence of sulphuric acid, the sensitiveness is 1:10,000. For the examination of neuralteine for the detection of adulterants, the following reactions are recommended. (1). 1 part of the substance should be soluble in 10 parts of water. (2). The solution coloured violet with ferric chloride should become blue and then green when added to sulphuric acid, but the lower layer of sulphuric acid should not be coloured yellow and should give no flocculent precipitate (presence of sodium salicylate). (3). The aqueous solution should give a precipitate composed of glistening scales on addition of sulphuric acid, and on further addition of a solution of nitrite, this should dissolve, with formation of a red coloration. (4). The aqueous solution when treated with glacial acetic acid should not give a precipitate either immediately or after standing for several hours.—A. S.

Abrastol (asaprol, calcium β -naphthol- α -sulphonate); A reaction of —. O. Carletti. Boll. Chim. Farm., 1909, 48, 223–224. Chem. Zentr., 1909, 2, 72.

A SOLUTION of abrastol in concentrated sulphuric acid gives an emerald-green coloration when treated with a few drops of a 10 per cent. alcoholic or aqueous solution of tartaric acid and then gently warmed. 0.00005 gm. of abrastol can be detected by means of this reaction, which has the advantage over the ferric chloride test of not being affected by the presence of organic acids.—A. S.

Pyrrole; Preparation of —. E. Khotinsky. Ber., 1909, 42, 2506–2507.

AN improved yield of pyrrole can be obtained by distilling ammonium mucate with glycerol instead of heating it alone. 50 grms. of mucic acid in the form of the ammonium salt were heated under the following circumstances. When heated alone, 2 grms. of pyrrole were produced. By adding 200 c.c. of glycerol, the yield was increased to 4.5–4.7 grms.; with 150 c.c. of glycerol saturated with ammonia gas, 6.5 grms. were obtained; whilst with 200 grms. of glycerol and distilling in a current of ammonia gas, there was a yield of 6.7 grms. of pyrrole.—F. SUDN.

Dicyandiamide; The chemical nature of —. N. Caro and H. Grossmann. Chem. Zeit., 1909, 33, 734–735.

IN contradiction to the conclusions of Radlberger as to the basic character of dicyandiamide, it is shown that

icyandiamide is not capable of forming salts directly, but that on bringing it in contact with acids, the molecule is completely changed, one molecule of water being taken up with the formation of diacyandiamidine which immediately combines with the acid present to form a salt. The reaction is:

Experiments with a 2 per cent. solution of diacyandiamide with different indicators showed that the presence of this compound had little influence upon the neutral reaction of the water. Measurements of the conductivity of a 0.3 per cent. solution showed only a slight increase over the conductivity of the water. Experiments upon the specific rotation of tartaric acid solutions showed that the addition of diacyandiamide had no influence; hence diacyandiamide has no basic properties. Thus it appears that diacyandiamide is a perfectly neutral compound, and this property explains why it so easily combines with other molecules to form complex salts.

—J. H. J.

tribromophenol; Behaviour of — to benzene in the presence of aluminium chloride. M. Kohn and N. L. Müller. *Monatsh. Chem.*, 1909, 30, 407—409.

When a mixture of tribromophenol (35 grms.), benzene (10 grms.) and aluminium chloride (35 grms.) is heated in the boiling water bath for 3 hours, bromobenzene (0.24 grms.) and phenol (2—5 grms.) are formed together with bromophenols. In a similar experiment carried out with trichlorophenol, interaction did not occur, but in the case of *p*-bromophenol a small amount of bromobenzene was detected.—J. C. C.

aldehydes; Oxidation of — by silver oxide. M. Delépine and P. Bonnet. *Compt. rend.*, 1909, 149, 39—41.

The presence of nitrates in no way affects the oxidation of aldehydes by silver oxide; accordingly, there is no need to prepare freshly precipitated and washed silver oxide as a preliminary, but silver nitrate may be added to the alcoholic solution of the aldehyde, and be then decomposed by addition of an equivalent quantity or slight excess of sodium or barium hydroxide. The action proceeds best if the silver salt be added in excess to the extent of from one-twentieth to one-half of the quantity theoretically required. The authors have readily obtained excellent results by this method with cinnamaldehyde, pyromucic aldehyde, citral, and other aldehydes.—J. T. D.

ethyl alcohol and its mixtures with water; Specific heat of —. A. Doroshewski and A. Rakowski. *J. Russ. Phys.-Chem. Ges.*, 1908, 40, 860—886. *Chem. Zentr.*, 1908, 2, 1568.

The absolute alcohol prepared by the authors had the sp. gr. at 15°/15°, 0.79426, and specific electric conductivity, $\kappa = 0.097 \times 10^{-8}$. The specific heat was determined by Schukarew's method (*Ann. der Physik*, [3], 59, 229), which is based on the fact that when different substances are introduced into an atmosphere of steam, the quantities of water condensed upon the surfaces of the substances are proportional to the specific heats of the latter. For absolute alcohol at 20° C. the value found was $c_{20} = 0.518$. For mixtures of alcohol and water the following results were obtained, the figures representing respectively, the percentage of alcohol by weight and the specific heat of the mixture over the interval, 22°—99° C.:—0, 0.6597; 94.43, 0.7089; 90.02, 0.7390; 85.05, 0.7732; 80.030, 0.8030; 74.99, 0.8309; 69.96, 0.8603; 64.96, 0.8859; 59.95, 0.9079; 54.93, 0.9296; 50, 0.9489; 44.95, 0.9702; 39.93, 0.9924; 34.98, 1.0116; 29.94, 1.0277; 24.97, 1.0411; 20.09, 1.0440; 15, 1.0422; 10.04, 1.0300; 0, 1.0169; 0, 1.0067.—A. S.

ethyl alcohol and water; Electric conductivity of mixtures of —. A. Doroshewski and M. Roshdestwenski. *J. Russ. Phys.-Chem. Ges.*, 1908, 40, 887—908. *Chem. Zentr.*, 1908, 2, 1568—1569.

In their experiments the authors purified the water by repeated distillation over barium hydroxide, potassium

permanganate, and phosphoric acid, and the alcohol by repeated distillation over quicklime. The results obtained at 15° C. were as follows, the figures representing the percentage of alcohol by weight and the electric conductivity ($\lambda \times 10^6$) respectively:—0, 1.097; 2.6, 0.949; 13.6, 0.540; 20.1, 0.414; 28.2, 0.313; 37.4, 0.256; 44.2, 0.237; 50.4, 0.234; 56, 0.219; 60.4, 0.223; 71.4, 0.235; 74.6, 0.238; 80.6, 0.248; 86.3, 0.235; 91.1, 0.215; 94.9, 0.196; 98.5, 0.133; 100, 0.097. The relation between the specific electric conductivity (λ) and the concentration (C) of alcohol in the mixture can be represented by the equation, $\lambda \cdot C^2 = a$ constant, which varies with the temperature and the degree of purity of the alcohol and water. The relation between the viscosity (η), the conductivity (λ), and the dielectric constant (D) of mixtures containing from 10 to 50 per cent. of alcohol, can be represented by the equation, $\frac{\eta \lambda}{D} = a$ constant.—A. S.

Alcohols and water; Indices of refraction of mixtures of —. A. Doroshewski and S. Dworzanczyk. *J. Russ. Phys.-Chem. Ges.*, 1908, 40, 908—931. *Chem. Zentr.*, 1908, 2, 1569—1571.

The authors have determined the indices of refraction of mixtures of ethyl alcohol and water for thallium and lithium rays at 15° C. and for sodium rays over the interval, 15°—55° C., also the indices of refraction for sodium rays of mixtures of water with propyl, isopropyl, butyl, and isobutyl alcohols respectively at 15° and 20° C. For the determinations at 15° C. the Pulfrich apparatus was used, whilst for higher temperatures the Zeiss immersion refractometer was employed. The more important results for mixtures of ethyl alcohol and water are given in the following table:—

Percentage of alcohol by weight.	$n_{15^\circ}^D$	$n_{30^\circ}^D$	$n_{40^\circ}^D$	$n_{50^\circ}^D$	$n_{55^\circ}^D$
0	1.33345	1.3318	1.3306	1.3290	1.3281
10	1.34020	1.3384	1.3368	1.3349	1.3339
20	1.34778	1.3450	1.3429	1.3406	1.3393
30	1.35470	1.3510	1.3481	1.3452	1.3435
40	1.35948	1.3550	1.3518	1.3484	1.3468
50	1.36290	1.3578	1.3543	1.3506	1.3488
60	1.36505	1.3597	1.3560	1.3522	1.3501
70	1.36645	1.3608	1.3570	1.3528	1.3505
80	1.36690	1.3611	1.3569	1.3525	1.3502
90	1.36626	1.3603	1.3561	1.3515	1.3491
100	1.36332	1.3573	1.3531	1.3487	1.3465

From the general results of the experiments it is concluded that:—(1). The maximum in the curve representing the indices of refraction of aqueous solutions of alcohols is more pronounced in the case of the iso than of the normal alcohol, and is also better defined the smaller the molecular weight of the alcohol. (2). The greater the molecular weight of the alcohol, the higher is the concentration of alcohol in the mixture showing the maximum refractive power. (3). Gladstone's formula, $\frac{n-1}{d}$, is the most suitable one for expressing the specific refractive power. (4). The influence of temperature upon the index of refraction of the mixtures can be represented by the equation, $n_t = \frac{n_n}{1+kt}$ (See also this J., 1908, 416.)—A. S.

PATENTS.

Lecithin; Process for obtaining hydrogen iodide and hydrogen bromide addition compounds of —. G. Richter, Budapest. Eng. Pat. 28,011, Dec. 23, 1908.

ADDITION compounds of lecithin with the halogen

hydracids are prepared by dissolving 1 kilo. of lecithin in 5 kilos. of carbon tetrachloride and saturating the solution with gaseous hydrogen iodide or bromide, while cooling with ice. The nitrogen of the choline residue combines with an excess of halogen, which is eliminated by stirring the solution with 50—100 gms. of calcined sodium carbonate; the product is finally filtered and evaporated *in vacuo*. The products are yellowish-brown, wax-like masses, containing 32 per cent. of iodine or 21 per cent. of bromine; they may be purified by dissolving in hot alcohol or acetone from which they separate on cooling. If the treatment with sodium carbonate be omitted, products containing still higher proportions of halogen are obtained.—J. F. B.

1. *p*-Dialkylamino-aryl-2:4-dialkyl-3-oxymethyl-5-pyrazolones; *Manufacture of* —. O. Imray, London. From Farbwerke vorm. Meister, Lucius, and Brüning, Höchst am Main, Germany. Eng. Pat. 4128, Feb. 19, 1909.

COMPOUNDS which are claimed to possess antipyretic qualities, are prepared by the action of alkylating agents on the *p*-aminoaryl-2:4-dialkyl-3-oxymethyl-5-pyrazolones. The starting point for the preparation of these bodies is the condensation of *p*-nitrophenylhydrazine with α -methylacetoacetic ester, whereby 1-*p*-nitrophenyl-3:4-dimethyl-5-pyrazolone is produced. This is converted into the trimethyl compound by treatment with dimethyl sulphate. By the action of bromine, this is converted into the 2:4-dimethyl-3-bromomethyl derivative, and the bromine is displaced by hydroxyl by the action of an alkali acetate and subsequent hydrolysis. Finally the nitro group is reduced by tin and hydrochloric acid.—J. F. B.

Camphor from borneols; Process for making —. Chem. Fabr. auf Actien, vorm. E. Schering. Fr. Pat. 398,361, Jan. 8, 1909. Under Int. Conv., Jan. 11, 1908.

BORNEOL and isoborneol are converted into camphor by heating, with or without a solvent, in presence of metals or their oxides, which possess the property of liberating hydrogen from the borneol; nickel and cobalt are especially suitable, and also cupric oxide, which is employed in insufficient quantity to oxidise the borneol. The metal is preferably added in several portions, as the action proceeds more regularly than when it is all added at once. For example, 10 parts of borneol, 30 parts of paraffin, and one part of petroleum are heated to 240° C. in an open vessel, and one part of nickel powder is added; when evolution of hydrogen has nearly ceased, four further additions, each of about 0.75 part of nickel, are made; the yield of camphor is said to reach 94 per cent.—T. F. B.

Therapeutic agent from myrrh; Process for obtaining a —. W. von Bolton. Ger. Pat. 211,212, May 17, 1907.

THE myrrh is extracted with water, the solution is evaporated, the residue is extracted with alcohol, and the alcoholic liquid evaporated. Or, the extraction with alcohol may be performed first, and the evaporation residue of the alcoholic solution extracted with water. In either case the product is a brown substance soluble in ether, melting at about 78° C., and possessing a very bitter taste. Its therapeutic action can be increased by boiling it with a solution of hydrogen peroxide, and then evaporating to dryness, preferably at 30—40° C. under diminished pressure, in order to avoid danger of explosion.—A. S.

Alkylthiosalicylic acids and their alkyl esters; Process for preparing —. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 211,679, Aug. 28, 1906. Addition to Ger. Pat. 203,882, Aug. 23, 1906 (see this J., 1908, 1223).

o-Diazobenzoic acid or one of its alkyl esters is treated with an alkali xanthate in presence of alkali; the resulting *o*-carboxylic acid or ester of "xanthogen phenyl ester," which need not be isolated, is readily converted into an alkylthiosalicylic acid or its ester by heating with an alkyl halide or an alkyl sulphuric ester in presence of alkali.—T. F. B.

Salts of arabic acid with bases possessing anæsthetic properties; Process for preparing —. E. Erhardt. Ger. Pat. 211,800, May 22, 1908.

ARABIC acid salts of cocaine, tropacocaine, stovaine, novocaine, and analogous bases, are prepared by the action of pure arabic acid on the base. They are intended to replace the hydrochlorides of the bases as anæsthetics.—T. F. B.

p-Aminobenzoic acid isopropyl ester; *Process for preparing* —. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 211,801, Feb. 13, 1908.

THE isopropyl ester of *p*-aminobenzoic acid possesses more powerful anæsthetic properties than the other known esters, but is less soluble. It is obtained by esterifying the acid or its salts with isopropyl alcohol or an isopropyl halide, or by the reduction of *p*-nitrobenzoic acid isopropyl ester or of a corresponding azo compound.—T. F. B.

Parine derivatives; Manufacture of new — and of intermediate compounds for use therein. P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 15,573, July 22, 1908.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENT.

Photographic negatives or positives on any sensitive surface; Process for developing and fixing in daylight —. F. Jeannot and M. Brenner. First addition, dated March 25, 1908, to Fr. Pat. 390,265, July 23, 1907 (see this J., 1908, 1046).

IN place of the pierate employed in the process described in the original patent, the reddish liquid obtained by boiling and expressing beetroots, is used.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Transportation of explosives. Eng. and Min. J., July 17, 1909. [T.F.B.]

THE lines comprising the American Railway Association, working 246,172 miles of line in the United States, Canada, and Mexico, have, beginning July 1, 1909, put into effect revised rules for the transportation of inflammable articles and acids. These are supplementary to the rules of the Interstate Commerce Commission, effective April 13, 1909, for the transportation of explosives. These regulations for the transportation of dangerous articles have been formulated by Col. B. W. Dunn,

U.S. Army, chief inspector of the Bureau for the Safe Transportation of Explosives for the American Railway Association, and are based upon an Act of Congress approved May 30, 1908.

The particular purpose is that the shipper shall know the true characteristics of his shipment and familiarise himself with the requirements of the regulations in order that he may inform the carrier by use of prescribed certificates and labels. Special supervision is given not only to the transportation of powder, dynamite and other heavy explosives, but it is now provided that special care shall be pursued in the handling of any material that gives off inflammable vapour at or below a temperature of 80° F.; materials subject to spontaneous combustion; materials other than acids, which are liable to cause accidents by friction, concussion, absorption of moisture, contact with organic matter and otherwise. Special rules so govern the handling of compressed gases as well as a list of eight of the more virulent acids and corrosive compounds. Illustrative of the detailed care with which the various rules have been formulated to govern the packing of different articles, are the following regulations:—

"Nitro-cellulose wet with solvent must contain not less than 30 per cent. of a solvent whose flash point is not less than 40° F.; and must be packed in strong lined or galvanised iron vessels, of the milk-can type, with a satisfactory means for keeping them securely closed.

"Metallic sodium or potassium, in quantity not greater than 1 lb., must be placed in neutral oil, and this in a well stoppered bottle protected by a tin box, or these substances may be packed in a hermetically sealed tin cylinder."

It is stipulated that every article of a hazardous character, when offered for shipment, must bear a prescribed red label to indicate to the railroad employees the method of handling (see also this J., 1908; 713, 834, 18).

Explosives; Report of the Chief Inspector of — for Western Australia, 1908.

The quantity and value of explosives imported into Western Australia for 1908 were as follows:—

Explosive.	Quantity.	Value.
		£
Gelignite	3,251,928 lb.	94,586
Dynamite	12,000 "	330
Blasting gelatin	438,500 "	17,712
Latex dynamite	339,852 "	11,726
Detonators	3,000,000 (number)	3,341
Fuse	547,872 (coils)	11,265
Blasting powder	116,500 lb.	2,896
Sorting powder	1,150 "	133
Other explosives	—	15,125
Reworks	—	312

A comparison is given of the importations of the different States of the Commonwealth for 1908:—

State.	Nitro-glycerin compound.	Blasting powder.	Sporting powder.	Totals.
	lb.	lb.	lb.	lb.
Western Australia	4,052,280	116,560	1,150	4,169,990
Victoria	1,457,200	195,390	42,070	1,694,660
Queensland	1,819,113	385,315	1,000	2,205,428
New South Wales	1,981,000	1,783,850	31,407	3,796,257
South Australia	772,000	123,300	8,985	904,285
Tasmania	564,100	69,480	10,859	644,439

Western Australia takes 31·08 per cent. of the total Commonwealth importations of explosives. No less than 12 tests for explosives were carried out during the year, and of this number 1445 were for gelignite alone, and 922 tests were made in connection with the special precautions which were taken to bring about a greater regularity and uniformity in the safety fuse used for blasting. There are 10 magazines (including Government buildings), in 43

explosives reserves, of an area of 3195 acres. The total capacity is 11,180 tons. Outside the reserves there are 36 magazines licensed, with a total capacity of 30 tons. The condition of the explosives imported into the State was, on the whole, very good. Some 260 cases of gelignite, 40 cases of gelatin dynamite, and 20 cases of blasting gelatin were destroyed owing to not passing the official test; 50 cases of gelatin dynamite were destroyed owing to chemical deterioration on storage; whilst some 600 coils of fuse were condemned owing to the fact that they hung fire, and did not comply with the regulations with respect to rate of burning.—G. W. McD.

PATENTS.

Nitration of cellulose; Method and apparatus for the — in the manufacture of powder, celluloid, and other materials: C. Crépelle-Fontaine. Fr. Pat. 397,707, Dec. 8, 1908.

The nitrating vessel is cylindrical in form, and is provided with an air-tight cover. Two acid reservoirs which can be either evacuated or placed under pressure are connected with the nitrating vessel. The pipe from one enters at the bottom of the nitrating vessel, and passes up the centre, delivering its acid at the top close to the cover. The other delivers its acid at the bottom of the vessel just beneath a perforated false bottom. The cellulose having been placed in the nitrating vessel, the air is withdrawn from it by evacuating one of the acid reservoirs. The cock communicating with the other reservoir is then opened, and the acid flows into the evacuated nitrating vessel. When this has been filled with acid, the cock is turned off and the acid which has been in contact with the cellulose is sucked off into the other reservoir. This process is repeated alternately and the advantages claimed are that a very much more uniform nitration of the cellulose is thus obtained.—G. W. McD.

Explosives containing hypophosphites; Preparation and use of —. E. Serrant and A. Boilleau. Fr. Pat. 397,792, March 7, 1908.

The hypophosphites of sodium, potassium, ammonium and calcium are claimed as explosives either alone or, preferably, in admixture with oxidising agents (10 to 50 per cent.). The advantages claimed are that they are stable, and have greater power than explosives generally employed, and produce no deleterious products on explosion.—G. W. McD.

Blasting powder; Wrappers for —. F. E. Thomas. Fr. Pat. 398,033, Dec. 30, 1908.

In place of the paraffined or parchment wrapper usually employed, it is proposed to utilise aluminium foil, or paper faced with aluminium powder. The advantages claimed are that in the case of explosives containing an excess of oxygen, the oxidation of the aluminium wrapper increases the strength of the explosive. The air space in the bore-hole between the cartridges is also reduced. The wrapper should weigh 4 to 12 per cent. of the weight of the cartridge itself.—G. W. McD.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Gooch crucibles for asphalt analysis; Preparation of —. B. Mears. J. Ind. and Eng. Chem., 1909, 1, 477.

The filtration of tarry or asphaltic precipitates suspended in organic solvents by means of the Gooch crucible, can be effected much more satisfactorily, it is stated, if a thimble of platinum gauze be inverted on the bottom of the crucible, and the fibrous asbestos disposed over the surface of the thimble. If the precipitate is not to be ignited, a copper gauze thimble may be used.—A. S.

Ether; Purification of and extraction apparatus.
R. Fritsch. Chem. Zeit., 1909, 33, 759-760.

back into R, and the latter is cooled at once by means of cold water. The ether so obtained is freed from water as usual with sodium and distilled.—A. G. L.

PATENT.

Vapours or gases of all kinds; Tube for the introduction of — into liquids. H. Stoltzenberg. Ger. Pat. 211,528, Feb. 21, 1908.

THE tube is intended specially for use in distilling with-steam. It is closed at the lower end and near this end is provided with a number of curved branch tubes (see Fig.) having fine perforations, through which the steam issues in a tangential direction.—A. S.

INORGANIC—QUALITATIVE.

Detecting nitrates in presence of bromides. Villedieu. See VII.

INORGANIC—QUANTITATIVE.

Nitrate- and nitrite-nitrogen; Determination of — in mixtures and in presence of organic matter. T. Zeller. Landw. Vers.-Stat., 1909, 70, 145-154. Chem. Zentr., 1909, 2, 148-149.

THE method is a modification of that of Gailhat (J. Pharm. Chim., 1900, [6], 12, 9). A suitable quantity of the liquid to be tested is boiled with a known quantity of ammonium chloride solution in a 100 c.c. flask until the volume is reduced to about 2 c.c. The residue is diluted to 100 c.c., and 40 c.c. are distilled with magnesia to determine the amount of undecomposed ammonium chloride. Another 40 c.c. are reduced with sulphuric acid and iron, and thus the nitrate- and ammonia-nitrogen present are determined. If the original solution contains ammonium compounds,

the ammonia is determined in a separate portion by distillation with magnesia. The method is inapplicable in presence of ferrous salts and carbonates; the latter may be removed by means of barium chloride before the treatment with ammonium chloride. The method is suitable for the examination of bacterin-cultures.—A. S.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Mixed solvents containing glycerol; Conductivity and viscosity of —. M. R. Schmidt and H. C. Jones. Amer. Chem. J., 1909, 42, 37-95.

GLYCEROL with water, or with methyl or ethyl alcohol, forms binary mixtures the properties of which are not additive.

In these mixtures, the conductivity curves of three electrolytes in no case obey the law of averages. The same is also true of the fluidity curves. The temperature coefficients of conductivity of solutions in pure glycerol are very large, and nearly identical with the temperature coefficients of fluidity. Glycerol, as a dissociating liquid, resembles water more closely than it does the alcohols. It is further found that conductivity increases with fluidity, but instead of increasing at the same rate, it varies as some fractional power of the fluidity.

Rare earths from mariupolite; Separation of —. J. Morozewicz. Anz. Akad. Wiss. Krakau, 1909, 207-213. Chem. Zentr., 1909, 1, 1965-1967.

THE minerals in which the rare earths occur, and which

are associated with the mariupolite (see Anz. Akad. Wiss. Krakau, 1904, 485), are beckelite and pyrochlore; the former contains metals of the cerium group and forms about 0.3 per cent. of the whole mineral, whilst the latter contains metals of the tantalum group, and is present to the extent of about 0.2 per cent. For the separation of the rare earths from the strongly preponderating oxides of iron, aluminium, and titanium, the following method was found satisfactory. By treatment with dilute hydrochloric acid, in which nepheline and beckelite are readily soluble, a separation was effected into a soluble portion containing the cerite earths, and an insoluble portion containing metals of the tantalum group, and also zirconium and titanium. (1). *Separation of cerium, lanthanum, didymium, yttrium, and cerium.*—The hydrochloric acid solution was evaporated, the silica separated, and then the solution again evaporated. The residual chlorides were converted into sulphates and heated until sulphur trioxide fumes were evolved, whereupon the residue was dissolved in cold water, and sufficient solid sodium hydroxide added to redissolve any precipitated aluminium hydroxide. The precipitate thus obtained consisted of hydroxides of the cerium metals contaminated with ferrie hydroxide. It was dissolved in hydrochloric acid, the solution diluted, and the hydroxides re-precipitated with ammonia. The precipitate was dissolved in nitric acid, the excess of acid expelled, and the faintly acid solution diluted with water to 50 c.c., warmed, and added drop by drop to a large excess of a hot concentrated solution of oxalic acid, in order to precipitate the oxalates of the cerite earths. In this way 0.21 per cent. and 0.06—0.07 per cent. of oxides of the cerium metals were obtained from two specimens of mariupolite respectively rich and poor in beckelite. (2). *Separation of niobic and tantalic acids.*—10 grms. of the portion of the mineral insoluble in dilute hydrochloric acid were heated in a platinum dish, on the water-bath, with 200 c.c. of water and 10 c.c. of sulphuric acid of sp. gr. 1.845, and hydrofluoric acid was added in small portions, until the whole of the mineral appeared to have dissolved with the exception of the zircon; this took from 10—12 hours to 2—3 days. The excess of hydrofluoric and sulphuric acids was then expelled, and the residue warmed with 200 c.c. of water; only the zircon and niobic and tantalic acids remained undissolved. The zircon was separated from the two acids by adding a few drops of concentrated sulphuric and hydrofluoric acids and filtering by means of a platinum funnel. From the filtrate the niobic and tantalic acids were precipitated by expelling the hydrofluoric acid, diluting with water, and boiling vigorously. A small part of the niobic acid sometimes remained in solution; hence, after filtering, the solution was treated with solid potassium hydroxide, the precipitate of ferrie hydroxide, together with hydroxides of any rare earths present, was separated, ignited, fused with potassium pyrosulphate, and the product extracted with cold water; on heating the solution for half an hour on the water-bath, any niobic acid present was precipitated. From 0.15 to 0.16 per cent. of niobic acid was obtained in this way from mariupolite. (3). *Separation of zirconia.*—The insoluble zircon, ZrSiO_4 , obtained in the separation of niobic and tantalic acids, was fused with sodium carbonate, whereby it was converted into zirconia and sodium orthosilicate: $\text{ZrSiO}_4 + 2\text{Na}_2\text{CO}_3 = \text{ZrO}_2 + \text{Na}_4\text{SiO}_4 + 2\text{CO}_2$. The sodium silicate was removed by extraction with water.—A. S.

Perbia; New method of isolating — G. Urbain.
Compt. rend., 1909, 149, 37—39.

With certain exceptions, the order of solubility of the salts of the rare earth metals is independent of the nature of the salts, the least soluble in any series being the salt of lanthanum, followed by the salts of cerium, praseodymium, neodymium, samarium, europium, gadolinium, terbium, dysprosium, holmium, yttrium, erbium, thulium, neoytterbium and lutecium. The nitrates with 5 molecules of water form one of the exceptions, that of gadolinium being the least soluble, those of neodymium and erbium next one another, and those of cerium and lanthanum being with those of neoytterbium and lutecium amongst

the most soluble. The author finds that the isomorphous bismuth nitrate is more soluble in nitric acid than gadolinium nitrate, less soluble than dysprosium nitrate, and very slightly less soluble than terbium nitrate. Accordingly, by adding to a mixture of gadolinium and terbium nitrates a very large amount of bismuth nitrate, and submitting to fractional crystallisation over a sufficiently long time, a perfect separation of gadolinium from terbium can be effected. The terbium compound obtained by the new method is equally pure with that formerly obtained by the author by fractional precipitation with dilute ammonia, and though the new method requires at least as much time as the old, the amount of labour involved is very much less.—J. T. D.

Colloidal silver solution obtained by the action of pure distilled water on metallic silver. M. Traube-Mengarini and A. Scala. Atti R. Accad. dei Lincei, Roma, 1909, [5], 18, I., 542—545. Chem. Zentr., 1909, 2, 179.

If pure water be boiled for a long time in a silver vessel containing some cuttings of silver, a colloidal silver solution is produced, which gives the characteristic appearance with the ultramicroscope. If the solution, whilst hot, be poured into a glass vessel, it becomes slightly turbid and acquires a faint reddish-violet colour, but if allowed to cool in the silver vessel, it remains perfectly clear. On addition of salts or acids to the solution, a white flocculent precipitate of metallic silver separates. Hydrogen sulphide produces a dark coloration. Copper is more easily attacked than silver by distilled water. Fresh-water fish when placed in pure distilled water which has been boiled in contact with cuttings of pure copper, die after a few hours.—A. S.

Uranium X; Separation and relative activity of —. B. Szilard. Compt. rend., 1909, 149, 113—115.

To a solution of 50 grms. of uranyl acetate in 1 litre of distilled water is added a solution of ferrie acetate in ammonium acetate and acetic acid. The mixture is heated, boiled for a few minutes, and rapidly filtered whilst still hot. The precipitate, which contains the greater part of the uranium X, is carefully washed, first with hot water and then with ammonium carbonate solution. The uranium X may be concentrated by dissolving the precipitate in acetic acid and repeating the above operation, but a better method is as follows: The precipitate is dissolved in hydrochloric acid and the solution is extracted with a large quantity of ether free from alcohol, which dissolves the greater part of the iron, and leaves uranium X in the aqueous solution. With either method of concentration, it is easy to obtain per gramme of uranium a product which gives an ionising current equivalent to that obtained from 0.03 gm. of uranium in radioactive equilibrium. The author concludes that the radioactivity of pure uranium X is equal to 10^9 times that of uranium in radioactive equilibrium.—O. R.

Trade Report.

The new American Tariff. Times Supplement, July 20, 1909. [T.R.]

THE American Tariff Bill has passed both Houses of Congress, and has been signed by President Taft.

SECTION I.

The following figures show the percentage of increase or decrease which has been made on the existing duties so far as they relate to chemical products, etc., e.g., an alteration in an *ad valorem* duty of 20 per cent. to 15 per cent. would be recorded as a reduction of 25 per cent.; an alteration from 5 cents to 2 cents per lb. would be recorded as a reduction of 60 per cent.

THE MAXIMUM TARIFF.

SECTION 2.

The following is a summary of the text of Section 2 of the proposed Tariff Law.

Sec. 2. That from and after the thirty-first day of March, nineteen hundred and ten, except as otherwise specially provided for in this section, there shall be levied, collected, and paid on all articles when imported from

any foreign country into the United States, or into any of its possessions (except the Philippine Islands), the rates of duty prescribed by the schedules and paragraphs thereto twenty-five per centum *ad valorem*; which rates shall constitute the maximum tariff of the United States [This is followed by granting power to the President to decide all cases where such rates are to be enforced, and to issue a proclamation accordingly. Provision is also made for the employment by the President of expert advisers.]

Although nearly all the changes made in the Chemical Schedule of the American tariff are in favour of the importer, every care has been taken to safeguard the interests of the home producers in continuation of the policy which matured in the McKinley tariff. The reductions in the tariff which have been made are merely indicative that the same high duties which may be required to build up an industry are not necessary to maintain it, and the circumstance that in some cases the duties have been reduced does not of necessity mean that better opportunities are offered to foreign competitors. Even the reduced rates are quite sufficient to give the home producer an important advantage, notwithstanding the higher cost of labour. The importer in America, and consequently the manufacturer in the United Kingdom, will be placed at some disadvantage by reason of the new method of valuation which requires the wholesale price in the United States to be taken as the basis for the assessment of duty, for this means that the duties on all those products assessed on an *ad valorem* basis, which have been left undisturbed in the schedule, have in effect, been raised. By taking the actual existing wholesale value of goods in the United States, instead of the selling price of the manufacturer in the exporting country, duty will be levied on freight and charges, as also on the profit of the dealer on the other side. In the case of heavy chemicals, however, this point is of no importance, as specific duties are charged.

The reduction of the duty on borax to 2 cents per pound is apparently an important one; but it was acquiesced in, and, in fact, recommended by American producers, who admitted that the old duty of 5 cents was much higher than was necessary for their protection. In practically every case in which a reduction has been made the same reason underlies it, and the concessions, if such they may be termed, are concessions to the American public, and not to the foreign manufacturer.

One of the important articles of export from Great Britain is ammonium sulphate, of which, according to American returns, America bought in 1907, 27,910 tons, on which the rate of duty was 0.3 cent per pound. At the tariff hearings the directors of the various agricultural experiment stations throughout the United States urged upon the committee the desirability of placing all plant foods containing nitrogen on the free list, on the ground that the duty on ammonium sulphate, which was equivalent to 1½ cents per pound of nitrogen in it, was enough to prevent its general use, and that it was not produced in the United States in such quantities as to meet the requirements of agriculture. These arguments carried weight with the committee, and in the House Bill the article was placed on the free list. On the other hand, the coke and gas companies made out a good case for retaining the duty. They showed that during 1907 the production of ammonia in various forms, all calculated as ammonium sulphate, was only about 100,000 tons, whereas they could produce 600,000 tons. They produced figures to show that the English market price for 1907 was, on an average, \$56.56; the freight, insurance, and brokerage was estimated at \$7, which made the cost of English sulphate, at New York, \$63.56. During the year 1907 the average price of English sulphate, at New York, was only \$61.93, however, hence the gas companies argued that English producers, in order to get rid of surplus products in the United States, sold at a sacrifice to the detriment of the American companies, and they argued that the removal of duty would encourage the erection of by-product coke ovens in England and retard it in America. These arguments prevailed with the Senate, and in the Senate Bill ammonium sulphate was

restored to the dutiable list at the decreased rate of wo-tenths of 1 per cent per pound. Subsequently, however, as a result of influential representations on behalf of the agricultural interests, at a late stage of the proceedings in the Senate, this product was placed on the free list, and thus restored to the position which it occupied in the House Bill. The reductions in duties on some of the alkalis and other heavy chemicals are also favourable to British producers, but it is questionable whether the difference between the old and new rates is sufficiently pronounced to make any appreciable difference in the volume of trade. The agitation for a lower tariff on chromates and bichromates of potassium and sodium was favoured on account of the position which these salts now occupy as the raw materials for the preparation of rust-inhibitive pigments for the protection of steel structures and fences. Ten thousand dollars were appropriated by the last Congress to cover the expenses of an investigation into this subject, and the discovery of the inhibitive properties of the chrome products is the result of the researches of the assistant director of the Office of Public Roads. The petition for a reduction of the duties was opposed by American manufacturers, and the Committee on Ways and Means, after considering the interests of both sides, recommended the slight reductions mentioned.

Taking as a whole the other articles on which the duties have been reduced, there are few instances where the alterations will have any noticeable effect on British industries. In fact, the position was well defined by Representative Harrison in the debate on the House Bill, when, affecting a thorough acquaintance with the chemical industries, he said:—"In almost all those instances (of reduced duties) the rates are still as prohibitive as ever."

Books Received.

GEWINNUNG UND REINIGUNG DES KOCHSALZES. Von Dr. CARL RIEMANN. Wilhelm Knapp's Verlag. Halle a. S. 1909. Price M. 3.20.

Svo volume containing 84 pages of subject matter with 20 illustrations. It forms one of Knapp's series of "*Monographien über chemisch-technische Fabrikations-Methoden*," Bd. XVIIII. The entire subject is sub-divided under the following heads:—I. Origin of the salt deposits. II. General remarks on the winning of salt. III. The search for, and exploiting of salt deposits. IV. Development by the sinking of shafts. V. Development by mining methods, &c. VI. The explosives used. VII. Conveyance of the rock salt, &c. VIII. Influx of water; mine waters, &c. IX. Ventilation, &c. X. Preparation of the crude salt. XI. Recovery from aqueous solution, &c. XII. Brine from various sources, and its treatment. XIII. Determining the salt in brines. XIV. Preparation of pure commercial salt from brines.

JAHRBUCH DER ELEKTROCHEMIE UND ANGEWANDTEN PHYSIKALISCHEN CHEMIE. Begründet und bis 1901 herausgegeben von Profn. Dr. W. NERNST und Dr. W. BÖRCHERS. BERICHTE ÜBER DIE FORTSCHRITTE DES JAHRES 1905. Herausgegeben von Dr. HEINRICH DANNEEL. Unter Mitwirkung der Herren Dtn. P. ASKENASY, P. BERL, K. ELBS, F. HARMIS, J. HESS, H. LEY, J. MEYER, M. ROLOFF und O. SACKUR. XII. Jahrgang. Wilhelm Knapp's Verlag, Halle a. S. 1909. Price M. 30.00.

LARGE Svo. volume, containing 968 pages of subject matter with 114 illustrations, and a bibliographic list of works on the following subjects:—I. Mathematics and Physics. II. Chemistry, chemical physics, and analytical chemistry. III. Biography, &c. IV. General, and Monographs. V. Periodical works. The work closes with alphabetical indexes of authors' and patentees' names, and subjects. With special regard to the subject matter, this is sub-divided and classified as follows:—I. PURELY

SCIENTIFIC SECTION. II. SECTION OF APPLIED ELECTRO-CHEMISTRY. I. THE PURE SCIENCE. (i), General. (ii), Books, &c. (iii), Apparatus. (iv), The periodic system, and the doctrine of valency. (v), Phase rule. (vi), Laws of velocity of reaction, and mass action. (vii), Catalysis. (viii), Thermochemistry. (ix), Theories of ions and electrons. (x), Osmotic pressure. (xi), Colloids. (xii), Solution phenomena. (xiii), Chemical and electrical energy, &c. (xiv), Theory of accumulators. (xv), Polarisation and electrolysis. (xvi), Electrical phenomena in gases, and Radioactivity. II. APPLIED ELECTROCHEMISTRY. (i), Production of current. (ii), Inorganic electrochemical processes and products. (iii), Carbides. (iv), Silicon and silicides, also borides. (v), Contact chemistry, and technical applications of the law of mass action. (vi), Metals. [Copper. Nickel. Zinc. Lead. Iron. Manganese. Ferro-alloys. Chromium. Tungsten. Vanadium. Titanium. Tantalum. Niobium. Cerium metals. Antimony. Arsenic. Tin. Platinum group. Gold. Silver.] (vii), Organic compounds. (viii), Alkali chloride electrolysis, and production of bleaching products and compounds. (ix), Apparatus for electrochemical technology. (x), Electric furnaces. (xi), Electro-treatment of ores. (xii), Galvano technology and allied branches.

THE HARMFUL EFFECTS OF ACETANILIDE, ANTIPYRIN, AND PHENACETIN. L. F. Kebler. U.S. Dept. of Agric., Bureau of Chemistry. Bulletin No. 126. Washington, 1909.

This Bulletin contains the results of an inquiry made by the Department of Agriculture to furnish information to the public to show them that acetanilide, antipyrine, and phenacetin should be employed with caution in the absence of medical advice. A summary of cases in which deleterious or fatal effects on health have been produced, shows that 1084 were due to acetanilide, 615 to antipyrine, and 193 to phenacetin.

MINES AND QUARRIES: GENERAL REPORT AND STATISTICS FOR 1908. PART I. DISTRICT STATISTICS. [Cd. 4751.] Wyman and Sons, Fetter Lane, E.C. Price 6½d.

This return, which forms the first part of the General Report on Mines and Quarries for 1908, contains statistics of the number of persons employed, the output of minerals, and accidents at mines and quarries in the United Kingdom arranged according to the inspection districts. The total output of the under-mentioned minerals in the United Kingdom in 1908, as compared with 1907, was as follows:—

	1907.	1908.
	Tons.	Tons.
Coal	267,830,962	261,528,795
Iron ore	15,731,604	15,031,025
Clays and shale	14,827,895	14,407,470
Limestone (other than chalk) ..	12,509,142	11,610,656
Igneous rocks	5,674,470	6,113,735
Sandstone	5,012,053	5,024,832
Chalk	4,779,387	4,261,585

MINES AND QUARRIES: GENERAL REPORT AND STATISTICS FOR 1907. PART IV. COLONIAL AND FOREIGN STATISTICS. [Cd. 4739.] Price 1s. 8d.

This part of the report includes statistics relating to persons employed, output, and accidents at mines and quarries in the British Colonies and in foreign countries during 1907.

New Books.

Abderhalden, Prof. Dr. Emil: Handbuch der Bio-chemischen Arbeitsmethoden. Bd. I. Allgem. Teil. Erste Hälfte. Mit 527 Textabbildgn. Verlag von Urban u. Schwarzenberg in Berlin und Wien. 1909. Preis M.18. (Das Handbuch soll 3 Bände umfassen. Der erste allgem. Teil wird in diesem Sommer vollst. vorliegen. Bd. II. u. III. erscheinen bis Herbst.)

Albrecht, Max, u. Albrecht, Ernst: Das Erdöl u. seine Produkte, Lagerung u. Transport von der Quelle bis zum Verbraucher. [Aus: "Das Erdöl."] (VIII, 151 S. m. 75 Abbildgn. u. 13 Taf.) Lex. Svo. S. Hirzel, Leipzig, 1909. M.7.50; geb. M.8.50.

Barber, Edwin Atlee: The pottery and porcelain of the United States; an historical review of American ceramic art from the earliest times to the present day; to which is appended a chapter on the pottery of Mexico. 3d. ed., rev. and enl., with 335 illustrations. Putnam, New York, 1909. c. 1893-1909. Price \$5 net.

Berkeley (Earl of), Hartley (E. G. J.) and Stephenson (J.): On the Osmotic Pressures of Calcium Ferrocyanide Solution. Part 2. Weak Solutions. 4to, sd. Dulau, London. Net. 1s.

Billiter, Priv.-Doz. Dr. Jean: Die elektrochemischen Verfahren der chemischen Gross-Industrie. Ihre Prinzipien u. ihre Ausführung. I. Bd. Elektrometallurgie wässriger Lösungen. Mit 117 Fig. u. vielen Tab. im Text. (VII., 284 S.) gr. Svo. W. Knapp, Halle, 1909. M.12.

Blyth (Alexander W. and Meredith W.): Foods: Their Composition and Analysis. 6th ed., thoroughly revised, enlarged and re-written. Svo. pp. 616. C. Griffin, London. 21s.

Bohr (N.): Determination of the Surface-Tension of Water by the Method of Jet Vibration. 4to, sd. Dulau, London. Net. 2s.

Guareschi, I: Enciclopedia (Nuova) di chimica scientifica, tecnologia e industriale, con le applicazioni a tutte le industrie chimiche e manifatturiere, alla medicina, farmacia, igiene, fisica, mineralogia e geologia, biologia, ecc., ecc., diretta dal dott. Prof. I. Guareschi con la collaborazione di distinti chimici italiani. Vol. V. Torino, 4^o fig., p. xii., 1248 e 6 tav. Lire 32.

Engler, Prof. C. u. Höfer, H. Das Erdöl: seine Physik, Chemie, Geologie, Technologie u. sein Wirtschaftsbetrieb. In 5 Bdn. Hrsg. v. Troff. C. Engler u. H. Höfer. Lex. 8^o. Leipzig, S. Hirzel. II. Bd. Geologie, die Gewinnung u. der Transport des Erdöls. Unter Mitwirk. v. Max Albrecht, Ernst Albrecht, Drs., Minist.-R. Joh. Holobek v. weil. Bergdir. Jos. Muck bearb. v. Prof. Hofr. Hans Höfer. Mit 307 Abbildgn. u. 26 Taf. (XX. 967 S.) 1909. M.36; geb. M.50.

Fichter, Fr.: Übungen in quantitativer chemischer Analyse. (138 S.) 8^o. Basel, F. Reinhardt 1909. M.2.40.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 16,198. Kyll. Rectifying column.* July 12.
16,500. Allgem. Briketierungsges. Briquetting and pressing material. [Ger. Appl., Aug. 26, 1908.]* July 15
16,523. Manlove, Elliott, and Co., and Liversedge. Apparatus for evaporating, drying, distilling, or crystallising. July 15.
16,546. Landau (Landau). *See under X.*
16,615. Irwin, and Johnson and Co. Hydraulic opening gear for filter presses.* July 16.
16,821. Neubäcker. Evaporating drum.* July 19.
17,088. Johnston. Filtering apparatus.* July 22.
17,192. Bonnel. Rectifier for distilling.* July 23.
17,220. Bennett. Distilling apparatus. July 24.
17,246. Boulton (Blair Engineering Co.). Regenerative furnaces.* July 24.
17,340. Anderson. App. for mixing or measuring liquid or other substances in definite proportions. July 26.
17,380. Müller and Bomhard. Process and apparatus for purifying gases.* July 26.
17,459. Lake (Freed, Krupp A.G. Grusonwerk). Separation of substances by the wet magnetic process.* July 27.
17,640. Harbord. *See under X.*
17,710. Ihner. Drying of materials or mixtures containing water. July 30.

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,139 (1908). Rigby. Drying cylinders. July 21.
15,000 (1908). Ridley. Obtaining gases from solids. July 21.
18,129 (1908). Kirkham, Hulett, and Chandler, Ltd., and others. Apparatus for effecting intimate contact of liquids and gases. July 21.
18,990 (1908). Williams, Snell, and Green. Rotary radiator for the cooling of liquids and gases. Aug. 5.
19,960 (1908). Knowles and Malone. Apparatus for the manufacture of crystals. Aug. 5.
20,381 (1908). Hewitt. Cooling or refrigeration of liquids or fluids. July 28.
24,859 (1908). Segalevie. Centrifugal separators. July 21.
25,829 (1908). Marks (U.S. Liquid Air and Oxygen Co.). *See under VII.*
37,57 (1909). Tebbutt. Treatment of materials by disintegration or pulverisation. July 28.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 16,217. Reynolds. Gas producers. July 12.
16,232 and 16,233. McMullen. Power gas producers. July 12.
16,239. Langhaus. Mantles for incandescent burners. July 12.

16,243. Kölmische Maschinenbau, A.-G., and Wegenscheidt. Gas purifiers.* July 12.

16,328. Weber. Manufacture of incandescence lamp filaments.* July 13.

16,355. Wilton. Treatment of gas obtained in distillation of carbonaceous materials. July 13.

16,356. Wilton. Gas generator plant. July 13.

16,357 and 16,358. Wilton. Carbonisation or distillation of coal or other carbonaceous materials. July 13.

16,925. Gibbons and Masters. Vertical gas retorts. July 20.

17,074. Lynn. Production of gas and ammonia from peat and like fuels. July 22.

17,112. Gibbons and Masters. Vertical gas retorts. July 22.

17,139. Roux. Converting peat into charcoal. [Fr. Appl., July 22, 1908.]* July 22.

17,348. Westgate. Retorts for gas making purposes. July 26.

17,420. Hiby. Treatment of gases produced by the destructive distillation of coal. July 27.

17,570. Crombie. Distillation of coal, peat, and wood. July 28.

17,572. Ward. Oil furnaces. July 28.

17,574. Pace. Manufacture of gaseous mixtures, more particularly air gas. July 28.

17,591. Lane. Construction and method of operation of hydrogen gas producing apparatus. July 29.

17,771. Laigle. Manufacture of filaments for incandescent gas mantles. [Fr. Appl., Aug. 1, 1908.]* July 30.

17,852. Durant. Method and apparatus for complete combustion of solid fuel. July 31.

COMPLETE SPECIFICATIONS ACCEPTED.

14,852 (1908). Trenzen and Pope. Manufacture of bodies of titanium, especially for electric incandescent filaments. July 21.

14,853 (1908). Trenzen and Pope. Manufacture of metallic filaments for electric incandescent lamps. July 21.

14,971 (1908). Sabatier. Manufacture of methane or of mixtures of methane and hydrogen. July 21.

22,033 (1908.) Zindler. Utilising bituminous brown coal and peat in making fuel briquettes. July 21.

24,893 (1908). Smith. Apparatus for producing water-gas. July 21.

26,121 (1908). Ely and Rollason. Treatment of coke. July 21.

27,045 (1908). Sabatier. Apparatus for making methane or mixtures of methane and hydrogen. July 21.

4860 (1909). Layton-Fisk. Incandescent gas mantles. Aug. 5.

5260 (1909). Fellner (Oberfeldt und Co.). Incandescent gas mantles. July 28.

5572 (1909). Ruddiman. Gas cleaners. July 28.

7780 (1909). Duff and Gas-Power and By-products Co. Gas producers. Aug. 5.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

16,357 and 16,358. Wilton. *See under H.*

16,464. Köhn. Vaporisation, distillation, and combustion of heavy hydrocarbon liquids. [Ger. Appl., July 15, 1908.]* July 14.

16,908. Davies and Richards. Treatment of liquid hydrocarbons. July 20.

17,030. De Fazi. Treatment of crude petroleum shale oil, and the like. July 21.

17,139. Roux. *See under H.*

17,209. Leaver. Apparatus for solidifying tar. July 23.

IV.—COLOURING MATTERS AND DYESTUFFS APPLICATIONS.

16,312. Wetter (Chem. Fabr. Grünau, Landshoff, und Meyer). *See under XX.*

16,377. Johnson (Badische Anilin und Soda Fabrik). Manufacture of derivatives of indigo colouring matter July 13.

16,799. Newton (Bayer und Co.). Manufacture of disazo dyestuffs. July 19.

16,996. Meister, Lucius, und Brüning. Manufacture of vat dyestuffs. [Ger. Appl., July 22, 1908.]* July 21.

17,265. Meister, Lucius, und Brüning. Manufacture of vat dyestuffs. [Ger. Appl., July 27, 1908.]* July 24.

17,546. Johnson (Badische Anilin und Soda Fabrik). Manufacture of colouring matter suitable for use as a pigment or lake. [Patent of Addition to No. 26,714, 1908.]* July 28.

17,818. Wyler and Levinstein, Ltd. New dyestuff derived from indigo and the production thereof. July 31.

COMPLETE SPECIFICATIONS ACCEPTED.

16,092 (1908). Newton (Bayer und Co.). Manufacture of disazo dyestuffs for cotton. July 28.

18,729 (1908). Newton (Bayer und Co.). Manufacture of dyestuffs of the azine series. July 21.

20,367 (1908). Newton (Bayer und Co.). Manufacture of basic dyestuffs. July 28.

21,911 (1908). Newton (Bayer und Co.). Manufacture of basic dyestuffs. July 21.

23,349 (1908). Newton (Bayer und Co.). Manufacture of azo dyestuffs. July 28.

24,605 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture and use of pastes of leuco compounds of indigo colouring matters. July 28.

4859 (1909). Wülling, Dahl, und Co. Azo dyes. July 28.

5792 (1909). Soc. pour l'Ind. Chim. a Bile. Manufacture of substantive azo dyestuffs. July 21.

6270 (1909). Chem. Fabr. vorm. Sandoz. Manufacture of blue to violet dyestuffs of the gallocyanine series July 21.

8154 (1909). Cassella and Co. Manufacture of rechromable dyestuffs. Aug. 5.

12415 (1909). Johnson (Badische Anilin und Soda Fabrik). Manufacture and production of azo colouring matters and intermediate products. Aug. 5.

15,088 (1909). Kalle and Co. A.-G. Manufacture of tetrabromindigo. Aug. 5.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS AND FIBRES.

APPLICATIONS.

16,285. Brierley and Melling. Dye-jigs, tanks, vats &c., used by dyers, bleachers, calico-printers, &c. July 14.

17,125. Mayo. Extraction of grease, &c., from an treating wool, skins, textiles, &c. July 22.

17,170. Walter. Recovery of benzine or other spirit used in making soft goods and in cleaning processes July 23.

COMPLETE SPECIFICATIONS ACCEPTED.

15,997 (1908). Gillies. Dyeing machines. July 28.

16,329 (1908). Kershaw and Cole. Apparatus for dyeing yarn and other fibrous material. Aug. 5.

16,689 (1908). Thomlinson-Haas, Ltd., and Standeven. Apparatus for drying or otherwise treating textile fibres, brics, &c. July 28.

19,276 (1908). Chandelon. Apparatus for the manufacture of glossy artificial threads. Aug. 5.

22,690 (1908). Newton (Bayer and Co.). Dyeing half-ool. July 21.

23,721 (1908). Turlur. Apparatus for drying yarns, etc. uly 28.

24,605 (1908). Johnson (Badische Anilin und Sodaabrik). *See under IV.*

25,312 (1908). Johnson (Badische Anilin und Sodaabrik). Production of resist effects and resist pastes for t dyeing. July 28.

26,616 (1908). Boulton (Edw. Esser et Cie.). Process and apparatus for dyeing yarn in hanks. Aug. 5.

27,742 (1908). Newton (F. Bayer and Co.). Printing th brominated indigo. Aug. 5.

4104 (1909). Friedrich. Production of ammoniacal pper oxide solutions for spinning artificial threads, etc. uly 28.

I.—COLOURING WOOD, PAPER, LEATHER, &c.

APPLICATION.

17,018. Faller. Process of dyeing wood and stone. wiss Appl., July 25, 1908.]* July 21.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

16,224. Bunet and Badin. *See under XI.*

17,074. Lynn. *See under II.*

17,216. Soc. l'Air Liquide. Liquefaction of air and separation into its constituents. [Fr. Appl., ly, 24, 1908.]* July 23.

17,318. Owens. Removal of carbonic acid gas from nes. July 26.

17,611. Serpek. Method of producing pure alumina. er. Appl., April 10, 1909.]* July 29.

17,642. Johnson (Badische Anilin und Soda Fabrik.) nufacture of ammonia. July 29.

17,690. Coulter. Process of manufacturing alkaline th sulphhydrates.* July 30.

COMPLETE SPECIFICATIONS ACCEPTED.

3426 (1908). Allgem. Elektrizitäts-Ges. Concentration ntric oxide. July 21.

13,458 (1908). Manufacture of lead oxide. Aug. 5.

16,963 (1908). Frank and Caro. Process for the nufacture of pure nitrogen from combustion gases. g. 5.

15,391 (1908). Dyes (Lehmann). Manufacture of rates. July 28.

17,246 (1908). Guttensohn. Production of briquettes of anganese ore. July 21.

19,738 (1908). Loesekann. Manufacture of artificial olite from fluorspar. July 28.

20,406 (1908). Johnson (Badische Anilin und Soda brik). Manufacture of compounds containing nitrogen l oxygen. July 28.

26,726 (1908). Caro and Scheele. Manufacture of amonium phosphate. July 21.

25,829 (1908). Marks (U.S. Liquid Air and Oxygen Co.). cess and apparatus for the liquefaction of gases moro ecially applicable to the liquefaction of air and its ration into oxygen and nitrogen. Aug. 5.

711 (1909). Herrmann und Co. Packing peroxides of alis for household use. July 28.

3189 (1909). Peniakoff. Manufacture of sodium sul- phate or other alkali sulphate. July 21.

6415 (1909). Mackenzie. Concentration of sulphuric acid and apparatus therefor. July 28.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

16,935. Martin. Treating clays for the manufacture of pottery and other articles. July 20.

17,264. Ingrams. Manufacture of refractory materials. July 24.

COMPLETE SPECIFICATIONS ACCEPTED.

12,974 (1908). British Thomson-Houston Co. (General Electric Co.). Machines for forming porcelain ware. July 28.

3546 (1909). Brightmore. Abrasive material and its manufacture. July 28.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

16,466. Soufflet. Artificial stone. [Fr. Appl., July 15, 1908.]* July 14.

16,588. Smith and Edwards. Method and apparatus for testing cements, &c. July 16.

16,602. Accettola. Manufacture of artificial marble. July 16.

17,002. Boucherie. Process for injecting wood.* July 21.

17,018. Faller. *See under VI.*

17,381. Lake (Pine Street Patents Co.). Process and app. for making cement.* July 26.

17,629. Seidner. Manufacture of artificial marble. July 29.

COMPLETE SPECIFICATIONS ACCEPTED.

24,718 (1908). Kayser. Method of making an acid proof cement. Aug. 5.

27,902 (1908). Von Medveesky. Process of producing a fireproof concrete compound. Aug. 5.

X.—METALLURGY.

APPLICATIONS.

16,210. Kunheim und Co. Metallic alloys Ger. Appl., Sept. 23, 1908.]* July 12.

16,211. Kunheim und Co. Pyrophoric metallic substances. [Ger. Appl., Jan. 25, 1909.]* July 12.

16,229. Loekwood and Samuel. Treatment of ores and the like. [Addition to No. 12,962 of 1908. Ger. Appl., Jan. 7, 1909.]* July 12.

16,300. Bullock and Calcott. Treatment of iron or steel to prevent rusting. July 13.

16,546. Landau (Landau). Apparatus for dissolving metals and other substances. July 15.

16,936. Holman, Holman, and Coad. Apparatus for treating metalliferous slime. July 20.

16,940. Heskett. Manufacture of steel.* July 20.

16,956. Büchel. Making slag easy to dissolve in the aluminogenetic extraction of metals. July 20.

17,102. Sulman and Durant. Recovery of zinc from its ores. July 22.

17,103. Dor-Delattre. Charging the retorts of zinc and analogous furnaces. [Addition to No. 13,822 of 1908.]* July 22.

- 9370 (1909). Paira, and Administration der Minen von schweiler. Production of soluble starch. July 28.

XVII.—BREWING, WINES, SPIRITS, &c.

APPLICATIONS.

- 16,318. Cooper. Making hop extract. July 13.
17,113. Faulkner, Collett, and Collett. Manufacture of uted materials. July 22.
17,206. Dymond (Topf und Soehne.) Apparatus for eeping, germinating, and kiln drying malt, &c.* July 23.

COMPLETE SPECIFICATIONS ACCEPTED.

- 20,086 (1908). Rogerson. Treatment of beer for sterili- tion and precipitation of the albumen. July 28.
5571 (1909). Ascoli. *See under XX.*

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

- 16,279. Epstein. Treatment of cocoa and chocolate. ly 13.
16,375. Ekenberg. Disiccation of milk and milk eparation. July 13.
16,757. Roffason. Conditioning or improving flour. ly 19.
17,003. Charronat. Food products formed from the ms of wheat and the like.* July 31.
17,271. Filbert. *See under XII.*
17,800. Woosnam (Wm. E. Whetham). Manufacture foodstuffs. July 31.

COMPLETE SPECIFICATIONS ACCEPTED.

- 15,552 (1908). Lloyd. Manufacture of aerated or carna- ted beverages at low temperatures. July 28.
24,425 (1908). Waldmeyer. Treatment of flour or und cereals. July 21.

(B.)—SANITATION; WATER PURIFICATION.

APPLICATIONS.

- 17,001. Dixon and Wilberforce. Methods and means for deodorising. July 21.
17,279. Thomson. Treatment of waste liquors. July 24.
17,649. Dodd and others. Production of inoculating substances. July 29.

COMPLETE SPECIFICATIONS ACCEPTED.

- 15,854 (1908). Cie. Française de l'Ozone. Purification of liquids by ozone. Aug. 5.
18,355 (1908). Reiser. Removing iron from water by means of air. July 28.

(C.)—DISINFECTANTS.

COMPLETE SPECIFICATION ACCEPTED.

- 16,982 (1908). Little and Morris. Manufacture of cleansing fluids for use as sheep-dips, for disinfecting, &c. July 21.

XIX.—PAPER, PASTEBOARD, &c.

APPLICATIONS.

- 16,220. Marx. Apparatus for saving pulp in making paper, also for concentrating pulp. July 12.
17,036. Von Kapff, and Nitritfabrik A.-G. Production of cellulose formate. July 21.
17,451. Reeser. Celluloid and articles made therefrom. July 27.
17,452. Reeser. Method for producing transparencies. July 28.
17,708. Summer and Hammond. Manufacture of wood-wool. July 30.
17,855. Egoroff and Remmer. Process for manufacture of all kinds of paper from sphagnum.* July 31.

COMPLETE SPECIFICATIONS ACCEPTED.

- 16,104 (1908). Sparre. Apparatus for treating fibres in the manufacture of paper. July 28.
17,967 (1908). Friedrich. Manufacture of cellulose structures. July 21.
19,276 (1908). Chandon. *See under V.*

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

- 16,312. Wetter (Chem. Fabr. Grünau, Landschoff, und Meyer). Manufacture of nitro-compounds and oxidation products of cyclic hydrocarbons and their substitution products.* July 13.
16,429. Newton (Bayer und Co.). Manufacture of new pyrimidines. July 14.
16,721. Zimmermann. Manufacture of acetyl deriva- tives of alkylated iminopyrimidines and of the alkyl- barbituric acids derived therefrom. July 17.
17,017. Bedford and Williams. Catalytic synthesis or deduction of organic substances. July 21.
17,171. Wellcome and Barger. Preparation of a physiologically active base. July 23.
17,655. Laroche and Juillard. *See under XII.*
17,830. Knoll and Co. Manufacture of purified extracts from aperient drugs. [*Ger. Appl.*, Aug. 24, 1908.]* July 31.

17,834. Gerber. Manufacture of alkyl ethers of phenols and other aromatic hydroxylic derivatives. [Ger. Appl. July 31, 1908.]* July 31.

COMPLETE SPECIFICATIONS ACCEPTED.

14,752 (1908). Lütkehermölle. Manufacture of isobornyl esters from pinene hydrochloride. July 21.

15,306 (1908). Kerfoot. Production of sterilised crystals of laxative salts. July 21.

18,049 (1908). Austerweil. Making borneol and borneol esters from pinene. July 28.

24,428 (1908). Newton (Bayer und Co.). Manufacture of a pharmaceutical compound. July 28.

314 (1909). Wellcome and Pyman. Manufacture of a therapeutic compound. July 21.

1560 (1909). Wellcome and Barger. Manufacture of a physiologically active base. July 21.

5571 (1909). Ascoli. Medical preparation from yeast. July 21.

9112 (1908). Bedford and Williams. Reduction of organic substances. Aug. 5.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

APPLICATIONS.

16,313. Palmer. Photographic screen plates for natural colour photography. July 13.

17,009. Newton (Bayer und Co.). Apparatus for the manufacture of photographic films. July 21.

17,324. Hollingsworth. Manufacture of sensitised albumenised paper. July 26.

COMPLETE SPECIFICATIONS ACCEPTED.

15,050 (1908). Caille. Photographic reproduction of colours. July 21.

27,686 (1908). Soc. Anon la Photographie des Couleurs, Sury and Bastyns. Preparing solutions used in the gum bichromate process of photographic printing. July 28.

7000 (1909). Triepel. Production of pigment prints. July 28.

XXII.—EXPLOSIVES, MATCHES, &c.

MR. HARRY SILVESTER, B.Sc., F.I.C., IN THE CHAIR.

MANUFACTURE OF IRON AND STEEL IN RELATION TO OTHER INDUSTRIES.

BY F. W. HARBORD.

In the industrial developments which the last 100 years have witnessed, I think we may claim that the great industry of iron and steel stands among the first. In 1806, just over a hundred years ago, the total production of the world did not exceed 800,000 tons of pig iron per annum, while in 1907 the annual production had reached the total of 58,973,000 tons of which 50,517,000 tons were converted into steel, a product unknown in the modern sense at the commencement of the nineteenth century. This enormous output of pig iron required approximately 129,000,000 tons of iron ore and probably not less than 95,000,000 tons of coal, apart from that used subsequently during its manufacture into wrought iron and steel.

I propose to consider the various causes which have assisted in these vast developments; how on the one hand the engineer and the chemist have made this progress possible, and how on the other the metallurgist, responding to the call of the varied modern requirements, has supplied the materials without which modern engineering developments would have been impossible.

It is clear that for the economic production of pig iron the essentials are cheap iron ores, cheap fuel, and suitable labour, and consequently the iron manufacturer is largely dependent upon the progress of mining engineering and cheap methods of transport for these materials. In 1806 a coal shaft 100 ft. deep was an object of wonder, whereas to-day, in a modern pit, 2000 tons of coal are raised per day and through one shaft from a depth of 1300 to 1400 ft., and in some instances mines are working at a depth of 4000 ft. The developments both in size and efficiency of modern pumping plants now render it possible for the mining engineer to face almost any volume of underground water at these great depths, while the winding engines, with which he is supplied, deal easily with the immense quantities of mineral at a maximum of speed and a minimum of cost. Rapid underground and surface traction and loading has reduced the cost of transport, and dressing has improved the value of the product, while the chemist with his modern explosives has enabled the miner to break ground in such quantities that his roads and hauling appliances can always be fully employed.

For raw material our modern iron and steel industries have been largely dependent upon the geologist and the prospector for the discovery of new deposits, and upon the mining and mechanical engineer for developing the ever extending areas of suitable ore and fuel for their consumption. Admitting, however, how much we owe to the mining and mechanical engineers, on the other hand, without the materials supplied by the iron and steel metallurgists, cheap mining would have been impossible; the demand of the engineer for materials suitable for his boilers and his steam-engines has been met by the metallurgist supplying him with a soft ductile plate for boilers, forgings of any strength required for engines, wire ropes of such a strength that deep haulage has been made possible, and steel castings of almost any shape and quality. Through the whole history of the industry it has been by mutual services rendered that progress on the one side has led to further progress on the other, so that while the engineer is ever, by improvement in design, obtaining greater

efficiency and thus reducing costs, the steel maker is ever supplying him with a material suitable for his requirements.

The products of iron manufacture are pig iron, wrought iron, and steel. The first, the product of the blast furnace, supplies the raw material for the other two, and they may be regarded simply as purified pig iron.

The blast furnace has been in use in England for the manufacture of pig iron from very early times in Sussex, Gloucestershire, and South Wales, in close proximity to the large forests then existing, whence charcoal was readily obtainable, but the modern blast furnace may be said to date from about 1735, when Abraham Darby of Coalbrookdale first successfully used coke as the fuel; an improvement which was rapidly taken up by iron manufacturers in the various iron districts near the coal measures. Since Darby's time the invention which has had the most far-reaching result has been the use of the hot blast introduced by Neilson in 1828, which has enormously increased the output and efficiency of the blast furnace, and coupled with this is the utilisation of the waste gases of the blast furnace, first for heating the blast for raising steam, and in comparatively recent times in internal combustion engines.

The reverberatory furnace for puddling iron was introduced by Cort in 1774, revolutionising the manufacture of wrought iron and practically superseding all others, while his invention of the grooved rolls in 1783 marked a mechanical advance which, when considered in the light of the present day steel works experience, has been even more far-reaching in its results.

At the commencement of the 18th century, the only processes of making steel were the crucible, invented by Huntsman in 1740, and the fusion of pig iron with its partial decarburization, by the joint action of blast and slag in an open fire on a hearth lined with charcoal. It is, however, the inventions of the Bessemer and Siemens-Martin open-hearth steel processes, which, coupled with the introduction of the basic lining by Thomas and Gilchrist, are the great landmarks in the development of steel manufacture during the past century, and will ever make it memorable in the annals of industrial progress.

In 1828, when Neilson first introduced hot blast, the average output of an ordinary furnace did not exceed 25 to 30 tons per week, and the coke consumption was not less than 45 to 50 cwt. per ton, and it is only by gradual steps that our present large production and low fuel consumption has been attained. This has been made largely possible by the engineering skill which has designed blowing engines enabling high pressure blast to be used, and by means of improved hoists, automatic charging appliances, and a hundred and one details, has so increased the output and reduced the labour costs, that probably the blast furnace to-day, in proportion to the weight of material it produces, is the cheapest industrial machine in the world.

The application of the Siemens regenerative principle to the heating of the blast as introduced by Cowper and Whitwell, and the complete utilisation of waste gases, has led to a great economy in blast furnace practice. As the result of very costly experiments, the best size of the blast furnace for the different classes of ore in different districts has been determined gradually, and a height of about 85 ft. and 20 ft. diameter at bosh has been found to be about the maximum limit for economic production. Above this size no increased output or economy in fuel is obtained, and the difficulty of getting coke sufficiently strong to stand the weight of the burden without crushing, and consequently the increased pressure of blast necessary to penetrate the burden, induces a tendency in the furnace to channel, and causes irregular working. Thus, those furnaces which were built 100 ft. and higher, have been discarded in favour of the smaller furnace.

The high pressure and high temperature of blast used in modern practice is very severe on the furnace lining, and the wear in the neighbourhood of the boshes was soon

found to be most serious. This was met by the device of water cooled blocks inserted in the brickwork of the furnace, by which means the life of furnace linings has been greatly increased. It is not too much to say that without the system of water cooling now generally employed, the rapid driving and large production of the American blast furnace plants would have been an impossibility.

Great improvements have been made in recent years in the delivery of the raw materials into the blast furnace. In place of hand filled barrows carried to the top of the furnace by inclined plane or vertical lift, and which then had to be hand tipped again on to the bell top of the furnace, the ore, flux, and fuel are now delivered from the chutes of bins into wagons on scales, and the weighed material is delivered automatically into the hoist skip, which travels up the inclined plane and automatically discharges the materials into the receiving hopper at the top of the furnace.

The economy of working is largely due to the great attention to detail, such as careful mixing of ores to insure a regular product, careful control of the temperature of the blast by means of pyrometers, and the most economic utilisation of the waste gases. Although the waste gases have for many years been utilised for steam raising and similar purposes, it is only during the last few years that they have been successfully employed in internal combustion engines. This problem presented considerable difficulties owing to the fine dust in suspension, but gradually, as the result of the labours of various inventors, methods of purification have been evolved, and in a number of works in this and other countries gas engines from 500 up to 2000 horse power are successfully employed and giving satisfactory results. In some iron and steel works where formerly the blast furnace gases did little more than raise the steam necessary to supply the power for the blowing engine, sufficient power is now generated to largely supply all that is required for the rolling mill and other plant of the steel works. In some cases the gas engine is utilised to generate electricity at a central power station in the works, which is then distributed to the various shops as required, whereas in others the gas engine may be employed as the motive power direct, as in the case of the blowing engine for a Bessemer or blast furnace plant. The economy thus effected by using the gases direct is most important and, in the case of those blast furnaces that have steel works attached, offers the possibility of making them nearly independent of outside supplies of fuel for power purposes. To those that have not facilities for utilising their surplus power in this way, especially if there are several blast furnace plants within a small area, the possibility of generating and distributing electric power to outsiders, for use either for lighting or power purposes, does not seem by any means an improbable development, when there is such a growing demand for cheap electric power in almost all industrial centres.

As a rival to the internal combustion gas engine, we now have the reciprocating steam engine in combination with the steam turbine, which, in the opinion of many competent judges, is likely to prove more efficient than even the gas engine. Some blast furnace plants are already equipped with steam turbines driven by steam raised by the waste gases, and possibly at no distant date, instead of having to use steam in our turbines, we may be able to employ the waste gases direct. The difficulties to be overcome are very considerable, but in view of the past engineering achievements, there seems nothing improbable in assuming that this will ultimately be accomplished.

Another question which is now receiving considerable attention is the dehydrating of the blast by cooling it to a temperature below zero before it enters the furnace. Furnaces for several years have been at work in America with the Gayley plant, and for over a year a plant has been in operation at Messrs. Guest, Keen, and Nettlefold's works at Cardiff with marked success. Opinions may differ as to the extent of the economy, but it is now generally admitted that the advantages direct and indirect of dry blast are very considerable, and had it not been for the costly nature of the plant many more furnaces would have been equipped with air drying plants before this. The

first cost is undoubtedly a very serious consideration, but from a recent visit to the Cardiff plant, and from the latest information obtainable, the advantages in lower fuel consumption, greater regularity of working of the furnace, and greater control over the production of iron of any required grade, seem to justify the expenditure, and it is probable that other plants will soon be installed in this country. As a minor matter, although one of no small importance in view of the large amount of room required for tipping, the utilisation of slag may be mentioned, and numerous attempts have been made to find some purpose for which it could be employed. To a small extent it has been used for cement manufacture and some excellent slag cement has been made, but this industry has not developed sufficiently to deal with any large proportion of the slag produced. It is used to some extent for ballast for railways and sidings, and the recent demand for waterproof roads has led to the introduction of Tarmac, which in the future will enable a considerable amount to be usefully employed. Broadly, however, no satisfactory method of dealing with anything like the large amount of slag produced has been suggested, and for the man who succeeds in relieving the ironmaster from the cost of tipping room, apart from actually paying him for his slag, a fortune is waiting.

In the preliminary treatment of ores in recent years there have been considerable improvements effected. In some works gas calcining kilns have been introduced with success, and considerable progress has been made in briquetting fine ores both in Sweden and this country. Briquettes can now be produced which are not only strong enough to bear carriage, but can withstand, without disintegration, the combined action of temperature and pressure to which they are subjected in a modern blast furnace.

The large production of the modern blast furnace in America has stimulated the English ironmasters to emulate the example, but so far not with complete success. In some cases the failure has been due to the different classes of ore used, but more frequently to trying to adapt our English plants to American conditions of working, when to obtain success a new plant especially designed with the accessories all duly proportioned would have been necessary. There seems no reason why a specially designed furnace working on 50 per cent. ores and high-class coke such as we have in this country, should not be able to turn out its 300 to 350 tons per 24 hours, but to do this, not only the furnaces, but the blowing engines, hot blast stoves, blast mains, charging appliances, and all other accessories must be duly proportioned, and unless one can start with a clear field it is not generally easy to arrange all these matters. The saving effected by ore bins with automatic charging appliances in which labour is reduced to a minimum may appear very inviting, but the expenditure necessary is so great that it is only justified by results when the capacity of the furnace, the blowing engine plant, and all accessories are such that the charging apparatus can be kept working to its full capacity.

Mistakes are sometimes made in this country by not fully realising that the economy in working, and the large production of certain plants, is due to the whole plant having been so designed that each part is in proportion, and that to increase the pressure or volume of blast is useless without a proportionate increase in hot blast stove capacity, facilities for charging, &c. The old question whether large outputs of American furnaces are not more than counterbalanced by the short life of the furnace, and whether our own practice of slower driving and longer life is not in the end more economical has been often discussed, but is really not a question which is worth serious discussion, except when a particular case can be considered. Generally speaking, American conditions of working are not possible in this country with our existing plants, and to attempt them is to court disaster; on the other hand, much progress has been made and is being made in our practice by modifying some of the American methods to suit our special requirements. Notwithstanding our many shortcomings it is no small satisfaction to know that in certain districts in England, working with extremely poor ores, we are producing pig

probably as cheaply as anywhere in the world. Closely connected with the economics in blast furnace practice are the great improvements that have been made in the manufacture of coke. The modern retort oven of the Otto-Hoffmann type produces a higher yield of coke than the old beehive oven at a greatly reduced labour cost, and the evolved gas is sufficient not only to coke the coal, but to leave a very considerable surplus for power purposes, which can be either used direct in internal combustion engines, or for steam raising, or for other purposes. The Siemens principle of regeneration is utilised in most of these ovens, so that the sensible heat in the waste gases is recovered, and heated air is supplied for the combustion of the gas round the retorts. In some plants the gas which comes off during the first stages of coking is taken off through what is known as the rich gas main, and used for illuminating purposes, and the gas which comes off later is taken through a separate main and used for heating the ovens. In the earlier forms of these ovens the coking of a charge took 26 to 30 hours, but by detailed improvements this has gradually been reduced to 20 hours, and in some ovens it is claimed that the average time does not exceed 18 hours. Great, however, as is the saving by the complete utilisation of the gases, to this has to be added the recovery of the by-products, tar, ammonia, and benzol. The ammonia may be recovered and sold as concentrated ammonia liquor, or it may be converted into sulphate. The tar may be sold as crude tar, or may be distilled for the recovery of the various tar oils where there is no local sale for the tar, but usually this treatment is better done at chemical works.

A plant of 100 coke ovens yields per year about 4,000 tons of tar, and nearly 3000 tons of sulphate of ammonia, and in 1907 over 95,000 tons of sulphate of ammonia were produced in England from blast furnaces, coke ovens, and producer plants, and very large quantities of tar. The value of sulphate of ammonia may be taken as £12 per ton, so that the recovery of this by-product alone represented a saving of nearly £1,140,000 to the community.

No reference has been made so far to the facility of transport, and yet nothing probably during the last 50 years has had more vital influence on our great industries. By means of our modern steam boats and mechanical means for charging and discharging cargoes, distances have been almost annihilated, and in our own country iron districts which otherwise must have ceased to exist have been maintained in a state of prosperity by the importation of ores from Spain and other countries many hundreds of miles away, at a cost little, if anything, exceeding that at which local ores were formerly raised in the spot. In America ores are brought from the Lake Superior district 800 miles by land and water to the coalfields of Pennsylvania, at a cost which enables this district to hold its own against the whole of the States. In no less a degree has cheap transport made it possible to distribute our finished products all over the world, thus greatly increasing the demand and making possible those great developments in railways and other large engineering undertakings, which are such a feature of the last 50 years.

The manufacture of wrought iron in the puddling furnace was carried on exactly as first proposed by Cort in a sand bottom, until the year 1818, when Samuel Falwin Rogers introduced the iron bottom to replace the sand, so that the iron could be worked in a bath of cinder or rich oxide of iron practically free from silica. This proposal was at first received with great indifference or considered impracticable, and it was only after much trouble and expense that it was given a fair trial, and the inventor never received the recognition which he deserved. Previous to this date the average production of the puddling furnace was about 8 tons per week, and by his device not only was the quality greatly improved, but the production of the furnace was very greatly increased. With this exception no important modification has been made in the puddling process, and it is carried on to-day as it was 90 years ago. Many attempts have been made to facilitate the operation by mechanical means, and much money and time have been spent in this direction, but none have been so successful

as to be generally adopted. The use of gaseous fuel in the puddling furnace also has never been a success, and the old coal-fired reverberatory still holds its own. In some other directions, more especially in the mechanical treatment, by the introduction of the direct acting steam hammer and sectional rolling mills, great advances were made and economies effected in the production of finished iron during the first half of the last century. In 1820 the first rail mill was introduced, previous to which time wooden or cast iron rails had been used. As railways gradually developed these gave a great impetus to the production of wrought iron for rails and other purposes.

In the manufacture of crucible steel little advance was made between its introduction by Huntsman and Robert Heath's process of reducing manganese oxide with carbon in the crucible during melting in 1839. In 1856 Vickers introduced the manufacture of steel castings, the far-reaching effects of which are hardly realised even to-day. Every year the methods of casting and quality of the castings are being so improved, that results are obtained equal in many cases to forged material, and finished products of such intricate shapes are produced that it would be impossible to make them in any other way.

The old coke-hole, practically the same as 100 years ago, is still largely used, although, comparatively recently, gas-fired furnaces on the regenerative principle have been introduced; and now electric furnaces are being employed on the Continent, and have in one or two cases been tried in this country.

The modern two regenerator gas-fired Siemens furnace or the Robinson-Pope furnace, capable of holding 10 to 12 crucibles, has been successfully used by various makers; the saving in fuel costs by their use is said to be nearly £2 per ton, but notwithstanding this saving they have not been generally adopted. The gas furnace is more costly to erect per ton of steel melted, but the chief objection seems to be that the same uniform heat cannot be obtained, and consequently all the pots are not ready to "teem" at the same time, and the quality of the steel varies; further, it is said that there is a greater absorption of sulphur from the gases than when steel is melted in coke furnaces, although from theoretical considerations this hardly seems possible. In my opinion it is only a question of time for the electric furnace to be largely adopted for the manufacture of what is now known as crucible steel, especially when charges of one ton and upwards can be conveniently dealt with, although for small quantities of 1 cwt. or less of special steels, the crucible will probably always hold its own. So far as the metallurgy of the crucible steel process is concerned, little change has been made, the highest classes of steel being still made from best cemented bars remelted in the crucible, or from mixtures of best Swedish iron recarburised in the pot. The demand for a cheaper quality of steel has led to cheaper materials being used for the second class qualities, and to-day large quantities of crucible steel are made from selected steel scrap, by melting this with Swedish pig iron or other recarburising material in pots. Special alloy steels, known as air-hardening steels, which are revolutionising our machine shops, are largely, although not exclusively, made in the crucible by melting suitable mixtures.

The vast developments, however, which have characterised the steel industry during the last 60 years are due almost entirely to the Bessemer, open-hearth and Siemens processes. These processes are worked to-day practically as when they were first introduced by their inventors, and, since Mushet showed the necessity of using ferro-manganese, there has been no metallurgical discovery of paramount importance to record with the exception of the basic process. Apart from this and some comparatively minor metallurgical improvements, the development of both processes has been entirely in the direction of increased size of converters, furnaces, and appliances. The discovery of the basic process, by which burnt dolomite replaced silica as a lining, marked a new era in the steel industry of the world, and made available for steel manufacture enormous deposits of phosphoric ores which were before unworkable. It also enriched the world by the recovery of the phosphoric acid, which these ores contained, in such a form that it could be largely

used for agricultural purposes. In the early days of the basic process it was generally considered that the phosphoric slag would have to be chemically treated to remove the iron and render the phosphoric acid soluble before it could be used as a manure; but experiments soon demonstrated that fine grinding was all that was necessary to render the phosphoric acid easily soluble in the soil, and that the iron and other constituents present had no deleterious effects. To-day the value of the slag is such that certain basic Bessemer works depend very largely for their profits on the sale of their phosphoric slag.

The effect of the basic process on the development of new districts is most marked in the case of Germany. Previous to 1880 the total production of pig in Germany did not exceed 2,500,000 tons, whereas in 1906 it had reached 12,293,825 tons, of which over 8,000,000 tons was basic pig iron made from local ores. With this exception, the development of the steel industry, like that of the blast furnace, is due far more to improvement in mechanical appliances and details of practice, than to new processes.

Our Bessemer converters have increased in size from 2 to 5 ton converter to 16 to 20 tons, and our open-hearth furnaces from 5 to 250 tons. In the early days of Bessemer practice the advantage of taking metal direct from the blast furnace and saving the cost of remelting in the cupola was recognised, but owing to the difficulties of obtaining metal of regular composition, and also of tapping the blast furnace at very frequent intervals, it was not generally used until the metal mixer or receiver was introduced. This is simply a large reservoir, sometimes gas-fired and sometimes not, in which metal from a number of blast furnaces is stored and is poured off as required into ladles and taken to the converters. These mixers, originally about 100 tons capacity, have been increased in size to hold 300 and 400 tons, and in one case in England 750 tons of molten metal. By mixing the products of several blast furnaces metal of very fair regularity is obtained, and to some extent a certain elimination of impurities effected; thus, the silicon is appreciably oxidised, and if manganiferous metal is mixed with metal high in sulphur, the sulphur can be considerably reduced.

The modern type of mixer is usually gas-fired, the air, if not the gas, being regenerated, and is similar in general construction to a large tilting open-hearth furnace; and it is becoming more and more the general practice to use this as a preliminary refining furnace by the addition of suitable fluxes. Many of these mixers are now basic lined, and, by the formation of suitable slags, not only can the metal be desilicified but largely desulphurised, matters of the greatest importance if the metal is afterwards to be treated by the basic process either in the converter or the open-hearth furnaces. For many years various attempts were made to use molten iron from the blast furnace or cupola in the open-hearth acid and basic furnaces, but without success, owing chiefly to the excessive wear and tear on the bottom. This was due largely to the irregular composition of the metal, and also to the method employed in the early days of making the hearths of basic furnaces, which were either rammed or bricked. Now the basic material is glazed on layer by layer, with the result that the very hard bottom, all fritted together, is well able to resist the cutting action of the molten metal. So far as the acid open-hearth process is concerned, there is probably little advantage in using molten metal, as it is not possible to add oxides of iron on the silica hearth of the furnace to effect rapid oxidation of the impurities, and it has not been generally adopted; in the basic open-hearth, provided a partially refined metal of regular composition from a mixer can be obtained, very rapid oxidation of impurities can be effected by oxidising slags, and considerable saving in time in the working of the charge is effected. Comparatively few early basic open-hearth plants had blast furnaces attached from which molten metal could be obtained, or probably its use would be more common to-day. Where there were blast furnaces there were no facilities for charging the open-hearth furnaces with the molten metal, and to provide these would have

necessitated in many cases the practical rebuilding of the melting shop, as the building would not have been strong enough to carry overhead cranes, or the open-hearth platform, to carry the ladle full of molten metal.

In modern Bessemer works, whether acid or basic, the practice is to take the metal from blast furnaces to a mixer and thence to the converter. The mixer is not expensive to work, as it requires little attention and the repairs are few.

In the open-hearth acid plants, when cold materials are charged, the increase in the size of the furnaces has necessitated mechanical charging, and this has been met by the Wellman charger and similar machines by which the materials are charged about 1 ton at a time from boxes. This has reduced the hard manual labour, and effected a great saving in the time of charging, thus considerably increasing the output and decreasing the fuel consumption.

In basic open-hearth works the best practice is to take molten metal, previously subjected to a preliminary refining in a mixer, direct to the open-hearth furnace, some of the ore and lime having been previously charged into the furnace by a Wellman charger, but in works where molten metal is not available cold materials must be charged as in the acid process. Attempts have been made many times to use an acid Bessemer converter in combination with basic open-hearth furnaces, and in some works the results appear to be satisfactory. The molten metal, either direct from the blast furnace or after passing through a mixer, is desilicified and partially decarburised and then transferred to a basic open-hearth furnace to be converted into finished steel. Provided the Bessemerising is stopped before any large percentage of the carbon has been removed, and that the metal is comparatively low in phosphorus, so that when the metal is transferred to the open-hearth furnace the proportion of carbon to phosphorus is relatively high, good results may be obtained, but in the case of high phosphoric metal the removal of carbon to any appreciable extent before transferring the metal to the open-hearth would, one anticipates, greatly increase the difficulty of obtaining regularly low phosphoric steel, as there would be considerable risk of the carbon being oxidised before the phosphorus. Within the last few years several important modifications of the basic open-hearth process have been introduced, but the only two of any practical importance are the Bertrand-Thiel and the Talbot continuous process. In the Bertrand-Thiel, either cold metal or molten metal from a mixer is largely dephosphorised and partially decarburised in what is known as a primary furnace, and when the carbon is reduced to about 1.5 to 2.0 per cent. and the phosphorus to about 0.2 per cent., it is transferred to a finishing furnace, in which scrap, oxide, and some lime have been previously heated, care being taken to prevent any of the phosphoric slag formed in the primary furnace passing into the finished furnace. This process was at work for some time on the Continent and in America, and later in this country at the Round Oak and Brynbo Steel Works, and no doubt excellent steel of very regular quality can be produced, but it has not so far been adopted at other works. One difficulty in adopting this process to an ordinary open-hearth plant is the transferring of the metal, as unless furnaces can be arranged one below the other, the molten metal would have to be raised to be poured into the finishing furnace, which in many cases might be difficult unless the plant were specially designed with a suitable overhead crane.

The Talbot continuous process involves the use of large tilting-furnaces, and molten metal from a mixer is charged and converted into steel in the usual way; instead, however, of pouring the whole charge, only a portion equal to about one-third of the contents of the furnace is tumbled, and then a ladle of mixer metal equal in weight to that removed is poured into the bath of finished steel remaining in the furnace. Oxides and lime additions are made in the usual way with a Wellman charger, and when the metal is dephosphorised and decarburised to the required extent, another third is cast into ingots and more mixer metal charged into the furnace. In this way the furnace is worked continuously, being, even

after the pouring of a charge of finished steel, always two-thirds full of molten steel, and it is only emptied at the week end. There are a number of furnaces at work or building, in England, on the Continent, and in America, and Mr. Talbot informs me that these furnaces when in full work will be capable of producing over 1,000,000 tons per year. There is no doubt that the quality of the steel is excellent, and the large outputs obtainable and small labour charges make it a very serious competitor with the ordinary open-hearth. The tendency seems to be to make the furnaces larger and larger, and a 250 ton furnace is now being erected in the North of England. These large furnaces, with necessary foundations and varied appliances for dealing with such large quantities of material, are necessarily very costly, and this is probably the principal reason why they have not been more generally adopted, as frequently it necessitates the entire reconstruction of the open-hearth shop.

In Bessemer practice the addition of oxides of iron in the basic converter by increasing the fluidity of the slag and decreasing the waste, although only a detail, is of some importance, and was first used in this country some years ago, although quite recently it has been described as a new modification in the technical Press. The more general use of mixer metal has considerably increased the yield, and also reduced the cost of repairs, but in other respects both acid and basic Bessemer processes are carried on as they were 20 years ago.

With the increased size of converters and furnaces, mechanical means have been devised for handling the large quantities of metal, and overhead cranes to carry ladles which hold 50 tons of metal are now common in large works. To deal with this large quantity of metal before setting has necessitated the casting of large ingots and all the mechanical appliances for dealing with these. Instead of 18 cwt. to 25 cwt. ingots, as was customary some years ago, 2 to 5 tons, and frequently larger ingots are now regularly cast, and the ingot moulds, instead of being placed in sunk pits, are frequently carried on cars on the floor level of the shop, and directly the entire heat is teemed, are drawn away by a locomotive to the stripper, where the ingot moulds are removed, and the ingots immediately taken away to the soaking pits or gas-fired reheating furnaces. This increase in the size of ingots has necessitated again larger reheating furnaces, and especially larger and more powerful rolling mills for cogging down and finishing, and more powerful engines for driving the mills. With the assistance of our engineers all these requirements have been met, and to-day rails 180 feet long are rolled in some of our large rail mills, and plates over 12 ft. wide in our plate mills. Not only, however, has progress been marked by an increase in size, but at every point mechanical devices have been introduced to save labour, increase the speed of working, and to reduce the cost of manufacture.

Previous to 1870, all rails were rolled in pull-over mills, and the maximum output was 100 per shift and rarely exceeded 50 tons. To-day a reversing rail mill with cogging, roughing, and finishing mill will turn out 250 tons per shift, and one works in England has rolled 1000 tons in a week, and another works, not in this country, but with which I am acquainted, has turned out 6000 tons. But it is not only in the special mechanical appliances connected with our industry that we have to thank our engineering friends, but also for providing us with engines capable of running at almost any speed, for our small mills, and reversing engines capable of withstanding the great and sudden stresses to which they are subjected, which are under absolute control, are steady in running, and easily handled and rapidly reversed.

To the engineers, also, we owe the great economies in fuel which have resulted from the use of high pressure steam—expansion, condensing, and compounding—economies which have been of the greatest importance to our industry in view of the large amount of power used in our works. As, however, the steam engine has displaced the water wheel, so now in its turn it appears to be in danger of being ousted by the dynamo and electric motor. We have already seen that it is no longer a question of steam engine *versus* gas engine for blowing our blast

furnaces, but the contest is between the gas engine and the steam engine combined with the turbine; and now we have electric driving for mills claiming the most serious attention of all practical steel works men. For many years we have been using electric motors for driving our cranes and for a number of subsidiary purposes, and now electrically driven mills are an accomplished fact. Both reversing and continuous mills are being electrically driven, and I believe I am correct in saying that in this district Sir Alfred Hickman has just completed the equipment for driving his rolling mills electrically. Now that the initial difficulties in the design of the electrical plant necessary to meet the special conditions have been overcome, there seems every probability that electrical driving will gradually but surely replace steam driving.

Again, if we consider the forging of large masses of steel which are necessary to meet the modern requirements of our latest battleships, we have to thank our engineers for the modern forging press, which has so largely replaced the steam hammer for the forging of our large guns and armour plates. Presses are now in use capable of giving pressure from 14,000 to 20,000 tons, and the work done by these is so much better than the hammer that the latter is gradually being superseded for heavy high class work, and even for small work the modern rapid forging press is gradually being adopted.

While, however, the engineer has, by his designs of improved machinery, made modern progress in iron and steel possible, it has only been so by the metallurgist supplying him with a material suitable for his machines, at a cost undreamt of a few years ago. Each year he is demanding a material of greater strength combined with greater ductility and making his specifications more rigid as regards the purity of the materials he uses and the mechanical tests it has to withstand. Thus, in railway materials we have to supply rails capable of resisting greater crushing load and resistance to wear, due to the greater weight of rolling stock and higher speed, axles and tyres which shall combine strength and rigidity with an absence of all tendency to brittleness, and steel for bridges and similar structures combining lightness, rigidity, and strength. For the moving parts of high speed engines, he demands material which is capable of withstanding reversal stress under all variations of speed without risk of failure.

We have only to consider some of our modern engineering structures, such as the Forth Bridge, or a modern Atlantic liner, to see how far the iron and steel makers have done their part during the last 30 years. Not only must the steel be as free as possible from impurities, but it must also be manufactured under such conditions that it is not over-oxidised, and further, that it is free from all mechanical defects. To fulfil these requirements there are two ways open to the steel makers—one to start with high price pig iron of exceptional purity, and the other to use cheaper material and purify during the manufacture. If the acid process is used, either Bessemer or open-hearth, it is well known that there is no dephosphorisation or desulphurisation during the operation, and to obtain a high class product, the manufacturer is compelled to use very specially selected irons, which are costly. On the other hand, if the basic open-hearth is used to obtain the same result, he has a much wider choice as regards his pig iron and scrap, and the problem that faces us to-day is the manufacture of steel, regular in composition and free from impurities, at a minimum cost. The most promising solution in my opinion is the use of the basic open-hearth for low phosphoric or what are commonly known as hematite irons. This has frequently been suggested, and is already being done at several works in this country, and various works in America and on the Continent, with excellent results, and there seems no reason why practically all our open-hearth furnaces should not be basic lined, irrespective of the pig iron used. I have long advocated this, and the only reason why it has not been more generally adopted, so far as I have been able to judge, is that most low phosphoric or hematite pig irons are usually somewhat high in silicon, and consequently are destructive to the basic hearth. There should, however, be no great difficulty in making pig iron of this class low in silicon and sulphur,

and at one of the works referred to, iron is being made of such regularity in these respects, that it is taken direct to the Talbot furnace without being passed through a mixer. This would at once give ironmasters a far greater range in the selection of their ores, as it would no longer be necessary to confine their purchases to ores with less than 0.035 per cent. of phosphorus, but anything up to 0.1 per cent. could be used. In those districts where phosphoric ores are obtainable, a certain proportion of these could be used with higher class ores, as absolutely reliable results in regard to the elimination of phosphorus could probably be obtained with pig irons containing up to 0.3 per cent. I am not suggesting that basic pig containing from 1 to 1.5 per cent. of phosphorus should not be used, but simply that, where hematite ore or other non-phosphoric ore is at present used, these should be treated in basic-lined instead of acid-lined furnaces. Working under such conditions, either with molten metal from a mixer or with cold pig iron and scrap, the quality of the whole of our steel at present produced in acid furnaces would be improved at practically no additional, but probably at a reduced cost, when the lower price of pig iron and the less risk of rejections are taken into consideration.

The Bessemer process, both acid and basic, has done such good service in the past that one feels loth to say anything which may seem to discredit a process which has served us so well, but at the same time we must face the fact that slowly yet surely both acid and basic Bessemer converters are being replaced by open-hearth furnaces. For boiler plates and many other purposes some engineers decline to have any Bessemer steel, and even for rails, open-hearth steel is now becoming a serious competitor with the Bessemer converter, and although the present Bessemer works may continue for many years to come, it is very unlikely that any other Bessemer plants will ever be erected in this country. More especially is this the case since the recent economies effected in the working of the open-hearth practice has reduced the margin between the cost of production, and to a very great extent left little advantage with the Bessemer process in this respect.

With regard to the Bessemer basic process, this, apart from any other consideration, is restricted by the phosphoric ores available. To work this process economically it is necessary to have a pig iron containing at least 2.25 per cent. of phosphorus and preferably 3 per cent., and the supply of ores to produce such a pig iron is limited to one or two districts in Great Britain.

The necessity of obtaining steel of exceptional purity for some purposes has led to interesting developments in refining in the electric furnace, and on the Continent this is being carried out at several works with marked success. Molten finished steel from either a Bessemer or open-hearth furnace is transferred to an electric furnace, where, by the addition of suitable fluxes, it is almost completely dephosphorised and desulphurised in about three hours. The furnaces are basic lined, and the refining is effected with very basic slags, the final desulphurising slag being practically free from iron. At two of the works I visited recently, one working with the Héroult and the other with the Röchling-Rodenhauser induction furnace, the phosphorus was reduced from 0.07 per cent. to 0.013 per cent., and the sulphur from 0.05 per cent. to 0.001 per cent. in three hours, with a consumption of about 300 kilowatts per ton of steel; an 8 ton furnace was refining about 50 tons in the 24 hours. Taking electric energy at the price it can be obtained in this country, the cost is by no means a prohibitive one. If the refining is not carried so far, less electric energy is required, and a considerably greater output is obtained. The possibilities of utilising electric furnaces in conjunction either with Bessemer or open-hearth furnaces for the production of steel for special purposes seems to offer considerable possibilities, as not only is the steel of exceptional purity, but with careful work it can be practically deoxidised. In steel castings, too, remarkably good work is being done in the electric furnace: castings of all sizes from a little over 1 lb. in weight and less than $\frac{1}{2}$ inch in thickness are being regularly made, equal in soundness and quality to anything produced from the crucible, and at a considerably less cost. All grades of steels can be made equal to high-class crucible steel, and

such steel is now being largely produced and competing with crucible steel. The increased size of our ingots with the accompanying segregation troubles, makes it doubly important that we should be able to produce the purest material, and so far, the best preventive for segregation is to have few impurities to segregate.

During recent years great advances have been made in the economy of fuel in our steel works for reheating and other purposes. The adoption of the Siemens regenerative system in many gas-fired furnaces, together with the use of vertical furnaces, sunk beneath the floor level, by which radiation losses are reduced to a minimum, has been attended with great economy in fuel, reducing the losses by oxidation and the labour of charging and withdrawing. In modern practice the sensible heat of the ingot as removed from the mould is practically sufficient, if allowed time to distribute itself equally through the mass, for clogging down, and in some cases for rolling the finished product, and in gas fired soaking pits very little gas is required for actual heating of the steel.

In numberless types of reheating furnaces great attention has been paid to details of furnace construction, both with a view to fuel economy and convenience for handling the materials, and the results have been most satisfactory.

Furnaces are now at work in which such a reducing atmosphere can be maintained that steel articles can be annealed at a red heat without appreciable surface oxidation, quite equal to anything obtained a few years ago by close annealing.

In the gas-producers, modifications in details of design by which the proportions of air and steam are made better control, have led to more perfect combustion and considerable increase in efficiency. The producer plant in a works has been in the past and even now is not infrequently neglected, and yet its systematic control is of the greatest importance. Not only should there be daily analyses of the gases produced, but a systematic record of the temperature of the gas as it leaves the producer, and an estimation of the percentage of carbon in the ashes, so that any losses may at once be detected and rectified.

We have now mechanical producers in which by stirrer and various other devices, the fuel is equally distributed and efficient combustion maintained, and others in which by-products are very largely recovered. The Mond producer is specially designed for by-product recovery, and the results obtained in this direction have been most satisfactory, the only drawback being the greater cost of the plant compared with an ordinary producer plant.

So far I have not referred to the question of alloy steels, and yet perhaps it is in this branch of steel manufacture that the greatest progress has been made from a metallurgical standpoint. From the discovery of manganese steel by Hadfield, to the recent developments in connection with high speed steels, there has been a record of steady progress. Our weapons of offence and defence depend entirely upon these special steels, and their special heat treatment by the metallurgist. To-day a Krupp cemented 6-inch armour plate affords resistance equal to more than 18 inches of wrought iron. There is ever the fight between the projectile and the armour, and some idea as to the shock these latter are required to resist may be gathered from the fact that the striking energy of a projectile from a 12 inch breech-loading gun is in some cases over 42,000 foot-tons, and if unencased is capable of penetrating 19 inches of Krupp cemented armour, and if capped 23 inches. The extraordinary properties of the projectiles now made, may be gathered from the fact that a 12 inch Krupp cemented plate has been pierced by a 12 inch armour piercing shell, and the projectile, after passing through the plate, has been found in the rear in a condition for bursting.

Our heavy guns are also made largely of special alloy steels, heat-treated to give them that combination of toughness and strength combined with ductility sufficient to avoid any risk of bursting.

For purposes too numerous to mention, nickel steels, chrome vanadium steels, molybdenum and other alloy steels, are used, and much of the success of our motor industry is due to the use of these special alloy steels.

for parts subject to vibratory and other stresses. The recent developments in high speed tool steel are so well known that they hardly need mentioning, but we have now alloy steels which are capable of cutting in a lathe at a rate of 500 feet per minute, and are revolutionising the machine shops of the world, thus enabling the metallurgist to make some repayment to the engineer for the many services which he has rendered to metallurgy.

The progress in the manufacture of steel alloys and the heat-treatment which is essential to their successful application is largely due to a number of workers on the theoretical side; without their labours the progress made would have been impossible. Amongst these may be mentioned Roberts-Austen, Osmond, Stead, Hadfield, Arnold, Le Chatelier, Guillet, and many others, who by their systematic researches on the constitution of steel and alloys have stirred the imagination and started

practical men thinking on these complex problems; and it is no exaggeration to say that their work is revolutionising various branches of our industry. The relation between the critical points and heat-treatment, instead of being a matter for academic discussion, is now made the basis of heat-treatment in actual practice, and I could mention works where the heat-treatment absolutely depends on previous accurate determination of critical points, and the results are largely controlled by the microscope.

It is by the intelligent application and adaptation to practice of the results of our scientific men that the future of the industry must largely depend, and provided our theoretical and practical men work hand in hand, each doing his part, there is every reason to believe that future developments will in every way equal those of the past, and that the present century will show a record of progress of which we may all be proud.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

[I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Filtering media and the like; Cleansing — J. Wilson, London. Eng. Pat. 15,019, July 15, 1908.

THE claim is for a method of cleansing the filtering medium of a filter, in which the filtration takes place by an upward flow of the liquid through such filtering medium. To effect the cleansing, the supply of liquid to be filtered is shut off and water is caused to flow downwards through the medium from above and at the same time air is forced through the perforated pipe by which the liquid to be filtered enters in the ordinary course. The air agitates the cleansing water and enables it to wash away the deposit.—W. H. C.

Mixing and filtering machines. W. S. Kern. Fr. Pat. 397,762, Dec. 19, 1908.

A HORIZONTAL perforated truncated cone is mounted upon a stand and has each end closed by metal plates, that at the larger end being easily removable. The material to be treated is fed through an opening in the smaller end of the cone and is mixed and agitated by brushes carried by arms fixed to a central shaft, which passes through the ends of the cone and is rotated by a pulley from without. The finer particles are brushed through the perforations, leaving the coarser ones on the interior surface. The latter are scraped off by blades fastened to the arms carrying the brushes, and are discharged through an opening in the plate closing the larger end of the truncated cone.—W. H. C.

Filter-press plates; Method of making thin — for oil, sugar, and chemical works. B. Degremont and A. Devaux. Fr. Pat. 398,065, Dec. 8, 1908.

THE plates are formed of a narrow iron frame with grooves on its inner edges. A thin corrugated metal sheet is held between two perforated plates which fit into the grooves, and a central aperture, strengthened by a metal ring on each side, is pierced through the plates for the admission of the liquid to be filtered and to afford support to the filter-cloth.—W. H. C.

Liquids and gases; Apparatus for effecting intimate contact of — Kirkham Hulett and Chandler, Ltd., and S. Hersey, London, and E. W. Blake, South Croydon. Eng. Pat. 18,129, Aug. 28, 1908.

THE gas enters through the opening, b^1 , and passes upwards through the central openings, f , from chamber to chamber, finally escaping from the top chamber through

the opening, c^1 . The liquid enters through the siphon, i , and flows down from chamber to chamber over the upper

edge of the upstanding pipes, *f*, finally escaping through the seal, *j*. The latter is also connected to each chamber by pipes, *k*, and taps, *k*¹, for the purpose of emptying the apparatus of liquid. In each chamber there is a domed disc, *d*, having its outer edge, *d*², turned upwards and perforated. The discs are mounted on the shaft, *c*, driven by the pulley, *e*², and each disc has several curved pipes, *g*, depending from it, so that when the discs are rotated, the liquid is scooped up by the pipes and is thrown off as spray through the perforations. The gas as it passes upwards is thus obliged to pass through the spray.

—W. H. C.

Introducing air or other gases into liquids. M. Schönmann. Fr. Pat. 398,060, Nov. 21, 1908.

The liquid is placed in a tank the bottom of which is covered by a plate having, on its upper surface, rows of gutters which cross one another at right angles. A round block formed of porous wood free from sap and hollowed out below, is placed over each intersection of the gutters, and the whole is covered by a plate having circular openings corresponding to the blocks. The edges of the openings are bent downwards and fit into grooves formed round the upper edges of the blocks. All the joints are made tight with asphaltum or pitch. Air, under pressure, is introduced by a pipe into the gutters and rises through the porous blocks in a finely divided condition into the liquid.—W. H. C.

Centrifugal separators. I. Segalevic, Budapest, Austria. Eng. Pat. 24,859, Nov. 18, 1908.

The claim is for a centrifugal machine which can be automatically emptied without stopping its rotation. A bell provided with external radial arms or blades at different heights, is fitted over the spindle within the drum. During the filling of the machine, the bell is coupled to the spindle so that bell, blades and drum rotate together. When the drum is full, the bell is disconnected from the spindle by means of a lever and ratchet, and is brought to a standstill by a brake. The drum continues to rotate and the blades on the bell detach the contents of the drum and discharge them through openings in the bottom of the drum.—W. H. C.

Drying air; Method of and apparatus for —. D. Baker, Philadelphia, Pa. U.S. Pat. 926,972, July 6, 1909.

The air is first compressed and then cooled to remove the heat due to compression. It is next further cooled whilst maintaining the compression, and the deposited water is mechanically removed. The temperature and pressure being still maintained constant, the air is passed through a measuring apparatus and delivered to the place where it is to be used.—W. H. C.

Furnace. T. S. Blair, jun., Elmhurst, Ill. U.S. Pat. 927,098, July 6, 1909.

A REVERBERATORY regenerative furnace is provided with a gas-port covered by a hollow metal hood projecting into the furnace from the end-wall and provided with an outlet in its rear-end portion. The hood is composed of united sections, insulated material on the upper side of the hood covering a joint. Water pipes placed outside the hood and connected with it, cause a flow of water through the inner end of the hood.—A. G. L.

Evaporating apparatus. W. and A. Ganlin, St. Cesaire, Canada. U.S. Pat. 927,520, July 13, 1909.

The liquid to be evaporated, is contained in pans supported on a frame over the flues of a furnace. By means of a device, controlled by a weight, the pans are progressively raised above the frame as the liquid in them evaporates, and at the same time dampers in the flues are lowered in order to regulate the evaporation.

—W. H. C.

Crystallisation; Disturbed —. H. Flamisset. Fr. Pat. 397,877, Nov. 27, 1908.

The solution to be crystallised is atomised by a current of air produced by a fan, and allowed to fall in the con-

dition of a fine spray into the crystallising vessel. The liquid is cooled by the air, and crystallisation takes place while the spray is falling.—W. H. C.

Agglomeration; Process of —. E. A. L. Rouxville. Fr. Pat. 398,083, March 13, 1908.

CLAIM is made for the use of hydrocarbons of the terpene series described in Fr. Pat. 356,716 of 1905 (this J., 1906, 83) and 378,251 of 1906 (this J., 1907, 1153) either in their natural condition or after vulcanisation, as an agglomerant.—W. H. C.

II.—FUEL, GAS, AND LIGHT.

Coal in Mull (Scotland). Times Eng. Suppl., Aug. 4, 1909. [T.R.]

LARGE seams of coal have been discovered in the island of Mull on the estates of the Duke of Argyll and of Mr. Clark, of Ulva. Mining rights have been granted to a syndicate, and operations have been begun near Bunessan by blasting an extensive seam quite close to the seaboard. This is the first effort that has been made in Mull to develop the coal resources commercially.

Coal-dust explosions. Times Eng. Suppl., Aug. 11, 1909.

DEMONSTRATIONS (in the presence of Lord Monkswell, chairman, and other members of the Royal Commission on Mines) of the explosive force of a mixture of coal-dust and air were carried out at the experimental gallery at Messrs. Pope and Pearson's Altofts Colliery, near Normanston, and were intended to show (1) whether an explosion can be confined to a coal-dust area by sandwiching it between two lengths distributed with stone-dust, and (2) to demonstrate the effect of an explosion of coal-dust without the mitigating influence of stone-dust. The series of experiments carried out at Altofts last year were mainly intended to convince mining engineers generally of the fact that finely divided coal-dust and air, without the presence of firedamp, constitute an explosive mixture of enormous power, and with that end in view they were undoubtedly successful. So far, however, they could only be considered as empirical, and the serious scientific investigation of the many ramifications of the problems involved had not been entered upon. Obviously the next step was to establish, if possible, the actual maximum force and the rate of development of an explosive mixture consisting of a finely divided solid and air, to be followed by the calibration of the effect of means of starving this force by depriving it of food and heat by the use of stone-dust zones and similar devices.

From November, 1908, to June 1, this year the work with the experimental gallery was suspended on account of atmospheric conditions. The interval was employed in designing and perfecting instruments for recording (1) the pressure produced by the explosion, (2) the velocity with which this pressure is developed, (3) the composition of the resultant gases, and (4) the temperature of the flame. When the experiments with the gallery were resumed in June, the committee had the assistance in their investigations, of several new instruments—(1) a pressure recorder, (2) a time recorder, (3) a measuring apparatus, and (4) separate forms of velocity recorders. The pressure recorder, or manometer, is so designed as to absorb any vibration arising from the experimental gallery without transmitting it to the recording mechanism. It consists essentially of a strong, triangular-shaped flat spring, against which there presses lightly a movable piston. This piston takes the form of a hollow cylinder and rests in a box containing oil. The pressure of the explosive blast acts upon the surface of this oil, and drives the piston against the spring. The end of the spring carries a hard steel point which marks its movement on a ruled surface revolving at a known speed. By this means a continuous record of the pressure is obtained from the first moment of its development. The speed of revolution of the drums carrying the ruled surface is obtained from a specially designed time marking recording tenths of a second. The time intervals of

one-tenth of a second are recorded simultaneously on the pressure charts by means of a delicate Deprez indicator, as two breaks in electric contact. The amount of displacement of the spring due to 200 lb. pressure is only half an inch, so that the records need to be read by means of a microscope and scale, so arranged as to enable pressures as low as 1 lb. per square inch and as high as 250 lb., to be easily measured. The rate of development and length of duration of pressure can also be determined by means of this instrument. The principle adopted for the velocity recorders is that of registering the time at which electrical contacts, placed at known distances inside the experimental gallery, are broken by the force of the explosion. These instruments give the speed of travel of the pressure. The average speed as shown by the experiments from the time of ignition to a point 275 ft. distant appears to have been 1400 ft. per second.

The evidence supplied by the several instruments described, appears to have confirmed what might logically have been deduced from previous experiments rather than to have afforded new information. This is illustrated by two experiments made on July 2 and 8 last. In each of these experiments a length of 275 ft. of the gallery was spread with coal-dust. In one case the succeeding length of 150 ft. to the open ("down cast") end of the gallery was spread with stone-dust, but in the other it was left undressed, constituting a so-called "dustless zone." A pressure recorder (X) was in each case placed at the end of the coal-dust zone 275 ft. from the point of ignition, and a second pressure recorder (Y) was placed 100 ft. in advance, or 375 ft. from the point of ignition and 50 ft. from the open ("down cast") end of the gallery. The coal-dust was raised and exploded in the usual manner by firing two cannon, as described in this J. 1908, 971. See also *ibid.*, 888. In the "dustless zone" experiment the pressure recorder (X) registered a rapid rise to a maximum of 45 lb. per square inch, and then fell—the rise and fall occupying about equal periods of time. The pressure recorder (Y), however, immediately upon being reached by the explosion wave, rose to a maximum of 113 lb. per square inch. In the "stone-dust zone" experiment the pressure curve registered by the pressure recorder (X) was practically identical with that of the previous experiment, but the pressure recorder (Y) on this occasion rose to only about 30 lb. per square inch, which gradually died away.

The explanation given for these divergent phenomena is that in the first experiment the coal-dust was driven in front of the explosion wave, so that the pressure recorder (Y) actually registered the pressure developed at the end of a coal-dust length of $275 + 100 = 375$ ft. In the second experiment the explosion was quenched by the stone-dust. In the former case the flame from the explosion shot out beyond the open ("down cast") end of the gallery to a distance of 16 ft., as shown by a specially constructed cinematograph. In the second case the flame penetrated the stone-dust zone for a distance of only 55 ft., as shown by tufts of gun-cotton suspended in the gallery. These experiments appear to prove conclusively that the stone-dust has a definite restraining action beyond the negative one of not supplying food for the explosion.

The Altofts investigation gives promise of supplying information which will be invaluable in the endeavour to prevent or minimize the effect of explosions in coal-mines, the success of which attempt must depend upon the thoroughness with which the phenomena attendant upon such explosions are understood.

A satisfactory instrument for determining the temperature of the flame of an explosion still remains to be devised, and in spite of the serious difficulties which the problem involves it is believed that success will be achieved. The information which such an instrument would supply is of very great importance and would lead to rapid progress.

Gas producer; Influence of steam and of loss of heat from the gas-producing zone on the efficiency of a —. J. Voigt. Z. angew. Chem., 1909, 22, 1539—1548.

The author takes the experimental results of Wendt (Mitt. über Forschungsarbeiten, herausgeg. v. V.d.I. II-ft

31), and bases upon them, calculations of the effect of the quantity of steam introduced, and of the loss of heat by radiation and conduction on the efficiency of a gas producer. He concludes that in order to attain the highest efficiency of the gas-producing zone and the highest temperature of combustion of the gas mixture produced, the total heat liberated by the combustion of the carbon by air, with formation of a mixture of carbon monoxide and nitrogen, must be utilised for the decomposition of steam by carbon, with formation of hydrogen and carbon monoxide. In practice the amount of steam introduced should be such that the proportion of carbon monoxide in the gas is a maximum. The loss of heat from the gas-producing zone by radiation has an important influence on the results obtained, but if this loss be kept low, the maximum efficiency is attained in most cases by using about 300 grms. of steam per kilo. of solid carbon, or 80 grms. of steam per cb. m. of air.—A. S.

Vertical retorts; Distillation in —. J. Bueb. J. Gasbeleucht., 1909, 52, 685—687.

In order to determine whether the gas evolved in vertical retorts ascends through the interior of the fuel column, or whether it passes through the coke in the neighbourhood of the walls, lighting gas was passed through a column of coke 6 cm. long in a porcelain tube heated to various temperatures. It was found that at temperatures from 500° to 900° C. the resistance to the flow of gas was increased; the heavy hydrocarbons in the gas were wholly or partly destroyed; the illuminating power of the gas was diminished, being entirely destroyed after passing through coke at 900° C.; and the calorific value was considerably reduced. The quantity of naphthalene in the gas was increased. Soot was deposited on the coke near the gas inlet, and this soot was only partly removed by the passage of a current of lighting gas mixed with steam. These experiments show that the gas does not pass through the incandescent coke in vertical retorts, or ascend in the neighbourhood of the walls, excepting immediately after charging, when the gas liberated near the walls is decomposed with formation of graphite. The gas may, however, pass up through the coke in the later stages of the distillation, when the heavy hydrocarbons have been liberated.—A. T. L.

Naphthalene in [lighting] gas; Determination of —, and its removal by cooling. J. Rutten. J. Gasbeleucht., 1909, 52, 694—696.

NAPHTHALENE in lighting gas may be determined by a modification of Colman and Smith's method, in which the solution of picric acid used, is saturated and contains crystals of the acid. When lighting gas is passed through this solution, the formation of the insoluble naphthalene picrate is quantitative, without further treatment, and after diluting the solution and re-dissolving the picric acid, the solution may be titrated immediately. The removal of naphthalene from lighting gas by washing the gas with tar is more effective the lower the temperatures of the gas and tar, since the vapour pressure of naphthalene decreases with temperature more rapidly than its solubility in tar. In the author's tests the gas was cooled by means of cooling chambers separated from the retorts by about 220 metres of piping. With the inlet and outlet temperatures of one of the coolers varying from 51° C. and 22° C. respectively, to 63° C. and 41° C., the quantity of naphthalene in the gas entering and leaving the cooler, varied from 1.142 and 0.504 gm. to 1.950 and 1.44 gm. per cub. m. It was also found that 50 per cent. of the tar and 70 per cent. of the naphthalene were removed in the cooling chambers.—A. T. L.

Peat for generating electricity in Germany. Bd. of Tr. J., Aug. 5, 1909, [T.R.]

THE following information is from the report by the British Vice-Consul at Emden:

An undertaking has been initiated near Aurich with Government assistance. Works are being erected with a view to utilising peat, of which a vast supply is available, for the generation of electricity. The Government will, it is reported, require a supply of some 2,000,000 kilowatts yearly in connection with the harbour at Emden.

PATENTS.

Cokes; Treatment of — B. Ely and A. Rollason. Pye Bridge. Eng. Pat. 26,121, Dec. 3, 1908.

COKE as they are withdrawn from the ovens are covered with a layer of coke breeze "of sufficient thickness to exclude air and moisture," whilst they are cooling down. It is stated that the coke when so treated becomes softened, and when employed as fuel in an open grate or a furnace, will ignite and burn with a steady flame. The softened cokes, so produced, can be ground and used in the manufacture of electric carbons or for other purposes.—E. F.

Combustion of fuel; Process for facilitating or controlling the — and for preventing smoke. P. M. Justice, London. From The Coal Treating Co., Boston, Mass., U.S.A. Eng. Pat. 14,558, July 9, 1908.

THE coal is coated with a very thin film of a salt which will not volatilise at 1000° F. but will, at that temperature or above, exert a catalytic action and accelerate the combustion of the carbon. The salts preferred, are calcium chloride or sodium nitrate, but salts of other alkali or alkaline-earth metals, or of copper, iron, manganese, aluminium, chromium, nickel, cobalt, tin, gold, and platinum have been used with similar results. A highly graphitic coal burning under ordinary conditions with flames not longer than 4 ins., when dipped in a weak solution of sodium nitrate or calcium chloride and dried, burned with flames 35 or 40 ins. long after the volatile matter was expelled and until the coal was practically consumed. The long flames do not appear until the temperature reaches 1000° F. It is essential that weak solutions of the salts should be employed; for example, solutions containing the salts in proportions varying from 1 in 600 to 1 in 10, according to the salt used. (Reference is directed to Eng. Pat. 1154 of 1907; this J., 1907, 752.)—A. T. L.

Suction gas producers. H. Berry, Clementston, Australia. Eng. Pat. 14,465, July 7, 1908.

To facilitate the removal of clinker and ashes while the producer is in operation, wells are provided at each side of the grate, into which the clinker and ashes are discharged by means of a rake passing through an air-tight gland in the outer wall of one of the wells. The wells are provided with suitable doors, and the gland for carrying the rake may be mounted on a universal joint. Instead of these wells, there may be openings controlled by sliding doors on each side of the grate and level with it, for discharging the clinker and ashes directly into the ash-pit.—A. T. L.

Methane, or mixtures of methane and hydrogen; Manufacture of — P. Sabatier, Toulouse, France. Eng. Pat. 14,971, July 14, 1908. (See Eng. Pat. 27,045, following.)

METHANE, alone or mixed with hydrogen, is prepared by passing water-gas over heated nickel. The use of moist water-gas as obtained by washing the crude gas with alkali hydroxide solution, is claimed, this condition rendering it unnecessary to specially introduce water vapour before passing over the heated nickel. The use of ordinary gas retorts, before the withdrawal of the incandescent coke, for the production of water-gas for making methane, is also claimed. It is stated that a water-gas containing 20 per cent. of carbon dioxide, obtained from light coke at 970° C., is just in condition for producing pure methane. The copper for freeing the water-gas from sulphur compounds should be kept at 500 to 600° C. After long use the copper becomes partly converted into sulphide and must be renewed; it may be roasted to oxide and then reconverted into metallic copper by heating in the gas to be purified. The temperature of the nickel used for effecting the reduction should preferably be 350, but may vary between 350 and 450° C.—E. F.

Methane, or mixtures of methane and hydrogen; Manufacture of — P. Sabatier, Toulouse, France. Eng. Pat. 27,045, July 14, 1908.

STEAM is passed over coke, anthracite or wood-charcoal kept at a constant temperature in tubes heated in a

furnace. In this way water-gas of constant composition is obtained. This is freed from carbon dioxide by washing first with sodium carbonate solution and finally with sodium hydroxide solution. It is then freed from sulphur compounds by passing it through tubes containing copper, heated in the same furnace as those in which the water-gas is produced, and is finally passed through flattened metal tubes containing side plates holding nickel, which are kept at a constant temperature in the same furnace as is used for the other reactions; in these, the conversion into methane takes place. The gas is then scrubbed and stored. The sodium bicarbonate solution produced from the sodium carbonate used for washing the water-gas, is reconverted into sodium carbonate by boiling on the top of the furnace, and then used again.—E. F.

Water-gas; Apparatus for the production of — with improved method of carburization by means of oil or other heavy hydrocarbons. H. E. Smith, London. Eng. Pat. 24,893, Nov. 19, 1908.

THE apparatus consists of two similar units which are worked together in an alternating manner. Each contains a water-gas generator, B, surmounted by a fireclay-lined channel, H, leading up to the charging hopper, G, G'. The channel, H, is surrounded by the system of checker brickwork, 1, which fills in the annular space between it and the outer lining, A, of the shell. Fuel is fed in from the hoppers, G, G', to the full height of the cylinders and raised to incandescence up to the level of the openings, X, by blowing in air from below; the escaping gases pass into the baffle-chambers, 1, together with excess of air coming from the secondary air-valves, MM', and raise the checker brickwork to a suitable temperature, escaping finally through the valves, SS'. The steam and air are now shut off, one of the gas valves, e.g., P', is opened, steam admitted to the baffle-chamber, 1, through the valve, T, in the other cylinder and the carburetting material through valve, U', to the baffle-chamber, 1, in the first cylinder together with a stream of water-gas introduced through pipe, V'. The steam is superheated in the chamber, 1, converting any carbon which may have been deposited in the chamber by the previous reverse operation into water-gas, passes through the fire in the generator, B, through the fireclay connecting pipe, J, into the adjoining generator, up which it passes, the long travel being conducive to a minimum of carbon dioxide in the resulting water-gas; this meets the mixture of gas and of carburetting material gasified in the baffle-chamber of this generator, and is thus carburetted, passing out through the fireclay-lined channel, and the usual condenser and scrubber. When the test flame shows that temperatures are getting low, the oil gas and steam valves are closed and the fires again raised to

suitable incandescence by the air blast just as at first; the air blast is then shut off, steam passed through the after-chamber in the second generator and through the two generators, and out by way of H. meeting carburetted gas produced in chamber. I. Operations are continued indefinitely in the same manner. The advantages of the apparatus are said to be that any carbon deposited in the carburetted gas is oxidised by the steam, which also cleans the injection and connecting pipes, that a shallow bed of fuel is used for the blow and deep one for the run, and that the heat contained in the gases produced during the blow is economically utilised.—E. F.

as-generator. R. N. McDonough and J. M. Conway, Fossil, Ala. U.S. Pat. 926,889, July 6, 1909.

HE claim is for a horizontal cylindrical retort set in a furnace and provided with a horizontal agitator. The retort is also provided with a valved feeding hopper at one end and with a valved discharge chamber at the other end. An auxiliary valved feed hopper formed by an extension of the cylinder is provided near the discharge hopper.—W. H. C.

as; Process of manufacturing —. B. Brazelle, Kirkwood, Mo., Assignor to H. Leschen, St. Louis, Mo. U.S. Pat. 928,103, July 13, 1909.

HE supply of air to a bed of hot coal is alternately opened and closed and the gases, consisting of the products of combustion when the air is admitted, are passed successively through a mass of mineral carbonates, a second mass of coal, and a mass of refractory material, and the resulting fuel gas is collected. When the air supply is cut off, the gases distilling from the coal are used through the same train of apparatus, a volatile hydrocarbon being injected into the gases before they enter the refractory material. The illuminating gas is collected separately. In some cases steam is injected to the glowing coal along with the air.—W. H. C.

as; Apparatus for generating hot compressed —. H. Neumann, Berg Gladbach, Germany. U.S. Pat. 928,324, July 20, 1909.

HE exhaust gases of an internal-combustion engine are delivered under pressure into a reservoir, and the compressed gases remaining in the clearance space of the engine cylinder are allowed to escape at a lower pressure for the next charge is admitted. The reservoir is fitted with a pressure-regulating valve controlled by the engine governor so that the pressure in the reservoir increases with the speed of the engine.—A. T. L.

liquid [liquefied] gas suitable for illuminating and heating purposes, and method of making said gas. L. Wolf, Boston, Mass. U.S. Pat. 928,729, July 20, 1909.

HE liquefied gas is obtained by cooling distillation gases — 25° C. under atmospheric pressure, in order to separate the constituents which are liquefied under those conditions, and then forcing the remaining constituents to a chamber filled with gasoline at a pressure of 1500 lb. per sq. in.—A. T. L.

producer gas; Method of generating —. H. F. Smith, Lexington, Ohio. U.S. Pat. 928,808, July 20, 1909.

HE gas obtained by passing air and steam upwards through a producer, is first cooled, and then passed through a separator to remove tar and water. The tar is discharged into the producer and converted into gas, and the water is allowed to run off.—A. T. L.

as producers; Grate for —, and means for removing ashes therefrom. H. F. Smith, Lexington, Ohio. U.S. Pat. 928,809, July 20, 1909.

A gas producer having a water-sealed ash-pit, the grate rests upon a ring which is suspended from the shell of the producer. The ring extends downwards into the water-stand and the space, thus enclosed beneath the grate, is provided with a blast-pipe, or with a gas-outlet pipe. A movable shoot, within which works a conveyor for

withdrawing the ashes, projects downwards through the shell of the producer and terminates below the water-level in the ash-pit.—A. T. L.

Incandescent mantles; Process of manufacturing —. A. Müller, Fürstenwalde-on-the-Spree, Assignor to G. P. Drossbach und Co., Freiburg, Germany. U.S. Pat. 927,374, July 6, 1909.

THE fabric of the mantle is impregnated with a colloidal solution of an "oxide-hydrate" of a rare earth.—W. H. C.

Incandescent mantles; Process for producing —. G. Buhlmann, Gross-Lichterfelde, Germany. U.S. Pat. 928,580, July 20, 1909.

A FABRIC of artificial silk is impregnated with a basic solution of a salt of a rare earth metal, prepared by adding small quantities of ammonia to the aqueous solution and shaking to re-dissolve the precipitate, these processes being repeated until the precipitate is no longer re-dissolved.—A. T. L.

Electric lamps; Soldering of the metallic filaments of —, to their electrodes. S. Marietti, Alpignano, Italy. Eng. Pat. 14,483, July 8, 1908. Under Int. Conv., July 8, 1907.

THE soldering of the filaments to their electrodes by means of the voltaic arc has hitherto been performed in an inert atmosphere, to avoid oxidation of the filaments. According to the present invention, oxidation is prevented by means of a current of air passing in a direction opposite to that of the filament, the process being conducted under ordinary conditions.—W. E. F. P.

Electric incandescent lamps; Manufacture of bodies of metallic titanium, particularly for filaments of —. C. Trenzen, Cologne, Germany, and F. R. Pope, Willesden. Eng. Pat. 14,852, July 13, 1908.

FILAMENTS consisting of practically pure titanium are obtained as follows: Titanic anhydride is saturated with ammonia in the cold and the product is heated in a vacuum to about 1200° C. The resulting mass is mixed with an organic binding medium such as a solution of casein in ammonia; the mixture is formed into threads and these are heated in electric furnaces up to 1200° C. The titanium nitride is thereby converted into cyanide and in the final treatment of the filaments in a vacuum by the passage of a high tension electric current, a filament of metallic titanium having a high melting point and high resistance is produced.—J. C. C.

Electric incandescent lamps; Manufacture of metal [tungsten] filaments for —. C. Trenzen, Cologne, Germany, and F. R. Pope, Willesden. Eng. Pat. 14,853, July 13, 1908.

RAW filaments are manufactured by allowing an aqueous solution or suspension of a tungsten-ammonium salt to flow through a narrow opening into a gel-forming medium, such as 99.8 per cent. alcohol, in which the hardening of the filament takes place uniformly. The form to be given to the filament is determined by suitable movement of the container holding the gel-forming medium or of the opening through which the solution flows. The filaments are heated in the usual way to about 450° C. in a vacuum and then electrically in an inert atmosphere or in a vacuum and so converted into metallic filaments.—J. C. C.

Measuring and recording device apparatus for gas analysis. Ger. Pat. 211,739. See XXIII.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Coal tar; Some constituents of —: *Alkylbenzene.* G. Schmitz and A. Sander. Ber., 1909, 42, 2633–2636.

THE authors have obtained a number of derivatives of ethylbenzene, extracted from coal tar. Dinitroethylbenzene, b. pt. 167.8° C. at 13 mm., was reduced by means

of ammonium sulphide to 2,4-nitroamino-1-ethylbenzene, which is very soluble in alcohol and when recrystallised from ligroin forms orange prisms of m. pt. 43°—44° C. Its acetyl compound melts at 100°—101° C. Trinitroethylbenzene was obtained by adding 10 grms. of ethyl-

(bomb calorimeter) 18,474 B.T.U.; it contained 0.62 per cent. of sulphur. The refining was effected by two slightly different methods, details of which are given. The yield of the different products from 100 galls. of crude oil are given in the following table:—

Product.	Quantity in gallons.		Sp. gr. at 60° F.		Setting point, in °F.		Melting point, in °F.	
	A	B	A	B	A	B	A	B
Heavy naphtha.....	1.62	1.45	0.7670	0.7670	—	—	—	—
Burning oil.....	10.04	11.50	0.7954	0.7955	—	—	—	—
Gas oil.....	14.87	13.04	0.8431	0.8450	25	25	—	—
Cleaning oil.....	2.83	1.56	0.8113	0.8705	26	26	—	—
Lubricating oil.....	9.58	11.03	0.8957	0.8935	30	30	—	—
Crude wax.....	2.26	2.21	—	—	—	—	112-26	111-34
Do.....	0.93	0.60	—	—	—	—	101	104
Do.....	—	0.16	—	—	—	—	—	84
Residuum from blue oil (refined).....	0.28	0.57	—	—	—	—	—	—
Residuum from treated crude distillate (refined).....	1.27	1.95	—	—	—	—	—	—

Method A.—Yield of refined wax of m. pt. 108.89° F., 2.907 galls.; sulphuric acid (sp. gr. 1.84) used in refining, 4.705 galls.

Method B.—Yield of refined wax of m. pt. 108.38° F., 2.707 galls.; sulphuric acid used, 4.68 galls.; burning oil, flashing point (Abel close test) 117° F.; lubricating oil, viscosity 200 secs. at 70° F. (Redwood).

benzene drop by drop to a cooled mixture of 40 grms. of nitric acid (sp. gr. 1.52) and 105 c.c. of sulphuric acid containing 25 per cent. of anhydride. The product crystallises in nearly colourless needles of m. pt. 37° C. When reduced with ammonium sulphide it forms *sym.* dinitroaminoethylbenzene, melting at 110° C. Additive compounds have been obtained of trinitroethylbenzene with *p*-toluidine, *o*-toluidine, monomethylaniline, *m*-xylylene (1,3,4.), benzidine, *o*-tolidine, β -naphthylamine, β -naphthylamine and naphthalene.—R. L.

American [Canadian] oil shales; Economic possibilities of —. C. Baskerville. Eng. and Min. J., 1909, 88, 149—154, 195—199.

AFTER a brief account of the shale oil industry in Scotland and elsewhere, the author refers to the large deposits of bituminous shales in New Brunswick, Canada. A description is given of the results obtained with 50 tons of low-grade run-of-mine oil shale from Westmorland County, New Brunswick, when tested in the experimental plant of the Pumpherson Oil Co., Scotland (see this J., 1897, 990). The retort was cleaned by distilling about 4½ tons of the New Brunswick shale therein, and then 36 tons 15 cwt. of the shale were retorted in 17 days. The results are shown in the following table:—

Date, 1908.	Weight of shale used.		Crude oil.		Yield per ton.	
	Tons.	Cwt.	Gallons.	Sp. gr.	Crude oil, gallons.	Ammonium sulphate, lb.
July 25a	2	4	95.85	0.885	43.57	58.55

	36	15	1473.28	—	40.99	76.94

a. Not included in average, as shale in previous test was not all out of retort until July 26th.

b. Condenser chest choked.

c. Condenser cleared.

The crude oil had the sp. gr. 0.92, flashing point 194° F. (90° C.), and setting pt., 54° F. (12.2° C.), calorific value

These results show that it is quite possible to utilise economically the New Brunswick shales, for the value of the by-product, ammonium sulphate, would more than cover the expense of mining and treatment. There are also deposits of shales in the United States, which might prove valuable under proper treatment. (See also this J., 1891, 136; 1893, 919; 1897, 876, 981.)—A. S.

Montanin and montana (montan) waxes. H. Ryan and T. Dillon. Proc. Roy. Dublin Soc., 1909, 12, 202—209.

THE commercial wax sold in Ireland as "montana wax" is said to be derived from peat, but differs widely in composition from the "peat wax" described by Zalosiedl and Hausmann (this J., 1907, 830); for the authors found it to contain a "free" acid melting at 83° C., and a unsaponifiable portion of m. pt. 58°—59° C. It also differed in composition from the wax extracted from peat by Krämer and Spilker (this J., 1902, 540), but was apparently identical with the montan wax prepared by von Boyen from Saxo-Thuringian lignite (this J., 1900, 728; 1901, 1221). The crude acid (*montanin acid*) in montan wax was found by Marcusson (this J. 1908, 850) to have an acid value of 143 and to be composed of insoluble hydroxy-acids melting above 100° C., and wax-like acid melting below 100° C. The montan wax examined by the authors was a yellowish, crystalline, wax-like solid (m. pt., 76° C.), which was readily soluble in hot alcohol, ether, chloroform, and petroleum spirit but was nearly insoluble in the cold solvents. It had a faint odour of petroleum. It had an acid value of 73.3 saponification value, 73.9; and iodine value (Hüf. Waller), 16.0. It was free from resin, and did not give the characteristic colour reactions of cholesterol. It yielded 47 per cent. of unsaponifiable matter, and 53 per cent. of crude montanin acid. The latter had an acid value of 138.3 and consisted, in the main, of an acid (C₂₄H₅₆O₂), with a molecular weight of 424, and a small quantity of an acid with lower molecular weight. The unsaponifiable matter crystallised from hot benzene in fine needles melting at 58°—59° C., and having a sp. g. of 0.92 and an iodine value of 31.13. Its elemental composition indicated that it was not a pure hydrocarbon but as it did not form an acetyl derivative on treatment with acetic anhydride it could not have contained appreciable quantities of primary or secondary alcohol. Montanin wax is a similar product, but differs greatly from montana wax in its physical properties. The sample examined was a white, hard friable wax with the following characteristics:—m. pt., 95°—97° C.; sp. gr. at 15° C. 0.980; acid value, 56.9; saponification value, 57.6 and iodine value, 10.5. It contained 34.8 per cent. of unsaponifiable matter, which was found to be identical with the unsaponifiable matter in montana wax. The other constituents were sodium montanate, 23.87; acetic montanin acid, 41.33 per cent. In the author's opinion montanin wax is prepared from montana wax by neutralisation.

ing part of the free acid with sodium hydroxide. *Irish lignite wax*.—A specimen of dried lignite yielded, on extraction with petroleum spirit, 0.24 per cent. of a rosinish wax, which had the following characteristics:—*n*. pt., 72° C.; *sp. gr.*, 0.989; acid value, 70.28; *m. pt.* of free acid, 80° C.; and *m. pt.* of unsaponifiable matter, 8°–59° C. All these values agree closely with the corresponding figures for montana wax.—C. A. M.

Oxidation of phenol. Gibbs. See XX.

Shale deposits of New Brunswick. Ch. of Comm. J., Aug., 1909. [T.R.]

It is reported that Dr. Ells, of the Geographical Survey, recently stated to the Senate Committee on Mines, at Ottawa, that the shale deposits of New Brunswick were richer than those of Scotland, from which the Standard Oil Company annually purchases 62,000,000 gallons of oil and 50,000 tons of sulphate of ammonia. The Scotch shale produces 30 to 40 gallons of oil per ton, and the New Brunswick, according to Dr. Ells, would produce from 50 to 110 gallons per ton.

PATENTS.

Detectors for the destructive distillation of coal or other carbonaceous substance. T. Parker, Wednesfield. Eng. Pat. 14,169, July 3, 1908.

A BUNCH or battery of vertical tubes is cast in one piece with common top and bottom flanges. Each battery of tubes is mounted as described in Eng. Pat. 4266 of 1908 (this J., 1909, 515), so as to have a single charging chamber and a single discharging chamber common to all the tubes.—A. T. L.

Acetate of lime: Process of making —. R. W. Erwin. St. Louis, Mo. U.S. Pat. 927,335, July 6, 1909.

A SOLUTION of calcium acetate is evaporated in a vacuum in a series of three vessels. It is concentrated in the first to a *sp. gr.* of 1.08, in the second to 1.12, and in the third to 1.16, or to the point of crystallisation, the crystals being subsequently dried in a vacuum.—F. R.

Extraction, purification and rectification of the volatile products of tar: Process for the continuous —. E. A. Barbet. Fr. Pat. 398,625, March 28, 1908.

THE crude tar is fed from an overhead store-tank into a tubular heater where it serves to cool the naphtha vapours and then passes down a column into a boiler where it is heated by high-pressure steam. The vapours pass into a rectifying column from which at different points very pure benzol, toluol, and xylol are separately withdrawn, condensed and cooled. The tar passes from the first boiler into a second similar one also steam heated, where the heavier naphthas are driven off and are condensed in the tubular heater mentioned above. The tar then passes through a series of stills, provided with agitators, set in brickwork. The last still of the series is heated by direct fire, the waste gases serving to heat the other stills. Carbolic oil, creosote and heavy oil are driven off, cooled in air condensers and collected, and soft pitch flows away continuously from the last still. The heavy oil may if desired be passed through a "cracking" still heated in a water bath in order to dissociate it into lighter products. The carbolic oil is passed continuously through a series of conical vessels packed with materials presenting a large surface and a stream of caustic soda solution is passed through the series in the opposite direction. Washed creosote issues from one end of the series and is, after treatment with sulphuric acid, fractionated in a continuous column still. The sodium phenate which issues from the other end of the series of washers is passed continuously through a decomposer where it is treated with acid or acid sodium sulphate and the separated crude tar acids flow away continuously into a store-tank. They are then passed down a continuous column still and fractionated.—W. H. C.

Bitumen and similar bodies; Purification of —. A. Mitchell. Fr. Pat. 398,159, July 7, 1908.

CRUDE bitumen containing a large proportion of mineral matter is heated along with water in a tank or boiler and bubbles are formed in the mass either by the action of the heat on the more volatile constituents of the bitumen, or by the addition of a small quantity of an acid which decomposes any mineral carbonates present, with the evolution of carbon dioxide. The bubbles of vapour or gas attach themselves to the particles of bitumen and float them up to the surface, forming a scum of bitumen and water free, or nearly free, from mineral matter. The scum is removed to another tank where it is heated to drive off the water.—W. H. C.

Purifying oils that have been used for lubrication. Fr. Pat. 398,411. See XII.

IV.—COLOURING MATTERS AND DYESTUFFS.

PATENTS.

Azo dyestuffs; Manufacture of new —. R. B. Ransford. London. From L. Cassella and Co., Frankfurt-on-Maine, Germany. Eng. Pat. 16,743, Aug. 8, 1908.

THE monoazo dyestuffs from 1,2,4-diazonaphtholsulphonic acid and α -naphthol can be transformed into new dyestuffs by the action of aromatic nitroso compounds. By using nitroso derivatives of the naphthalene series, dyestuffs are obtained which yield on wool by after-treatment with chrome, shades ranging from bluish to greenish blacks of good fastness; from the nitroso compounds of the benzene series, products giving reddish-black shades result. Example:—39.4 kilos. of the dyestuff obtained from 1,2-diazonaphthol-4-sulphonic acid and α -naphthol are heated to the boil with 800 litres of water, and after adding 10 kilos. of sulphuric acid (66° B.), a paste containing 17.3 kilos. of nitroso- β -naphthol is gradually introduced. After heating for about half an hour, the nitroso compound disappears. The new dyestuff is then salted out.—P. F. C.

Dyestuffs of the Gallocyanine series; Manufacture of new blue to violet —. Chem. Fab. vorm. Sandoz, Basle, Switzerland. Eng. Pat. 6270, Mar. 16, 1909. Under Int. Conv., Sept. 24, 1908.

CLAIM is made for new dyestuffs of the Gallocyanine series by condensing the Gallocyanine obtained from nitroso-dimethylaniline and gallic acid with resorcinol in alkaline solution in the presence of an oxidising agent. Example I:—34 parts of the above Gallocyanine hydrochloride are dissolved in 500 parts of water and two molecular proportions of sodium hydroxide; 25 to 34 parts of resorcinol are then added, and the whole is stirred for about three days at the ordinary temperature, in the presence of a current of air. The mass is finally heated to 90° C. and is filtered and washed. The dried product is a crystalline powder with a bronze lustre. In a second example (in which 20–30 parts of resorcinol are used, the quantities of the other ingredients being the same), the mixture is heated at 60–70° C. for two to three hours in a current of air. The product forms small green leaves with a metallic lustre. The sulphonated dyestuff of Example I. dyes chromed wool blue, and that of Example II. produces a violet shade. The leuco-compound of the colour-base of Example I. gives blue shades on cotton mordanted with chromium, whilst that of Example II. gives violet shades. (See also Eng. Pat. 6272 of 1909; this J., 1909, 832.)

—J. C. C.

Ink. R. W. Hochstetter, Assignor to the Ault and Wiborg Co., Cincinnati, Ohio. U.S. Pat. 928,450, July 20, 1909.

AN ink that can be used with wax stencil sheets, is prepared by grinding an organic pigment with glycerin or a mixture of glycerin and a sulphonated oil, such as Turkey-red oil. The pigment, which should not be soluble in, or chemically react with glycerin, may be prepared with a base of barium sulphate.—C. A. M.

Ink. R. Hochstetter, Cincinnati, Ohio. U.S. Pat. 928,915, July 20, 1909.

AN inorganic pigment (insoluble in, and not capable of chemical interaction with, glycerin) is ground up with a mixture of glycerin and a sulphonated oil, such as Turkey-red oil.—C. A. M.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

Abaca fibre; Tensile strength of machine- and hand-stripped —. R. F. Bacon. Philip. J. Sci., A, 1909, 4, 163—165.

EXPERIMENTS made by the author show that machine-stripped abaca fibres are stronger than those stripped by hand.—F. SODX.

PATENTS.

Threads and filaments of cellulose; Manufacture of —. A. Lecœur, Rouen, France. Eng. Pats. 14,143, July 3, 1908, and 28,149, Dec. 24, 1908.

SOLUTIONS of colloidal hydrated cuprammonium oxide can be prepared in two ways; firstly, by treating a solution of a copper salt with ammonia and caustic alkalis with subsequent dialysis of the solution, and secondly, by the simultaneous action of air and ammonia on metallic copper with subsequent dialysis as described in Eng. Pat. 16,442 of 1906 (see Fr. Pat. 374,277; this J., 1907, 761). The liquors thus prepared will be hereafter referred to as liquors A and B respectively. If liquor A is so prepared as to contain more than 12 grms. of copper per litre, it contains deleterious compounds which cannot be removed by dialysis. A solution containing only 12 grms. of copper per litre is however only capable of dissolving 30 grms. of cellulose, and this proportion is too small for the manufacture of a sufficiently strong filament. It is found that the best product is obtained if a mixture of the two liquors be employed, the proportions being such that the resulting mixture contains about 25 grms. or more per litre of copper in the state of colloidal hydrated cuprammonium oxide, but of which no more than about 12 grms. of copper per litre is derived from liquor A.—P. F. C.

Artificial silk and like threads; Apparatus for use in the manufacture of —. H. G. Tetley, London, and J. Clayton, Braintree. Eng. Pats. 19,157 and 19,158, Sept. 11, 1908.

ACCORDING to these inventions, the hollow spindle, which is rapidly rotated, is carried on a swinging frame so that when the nozzle is moved into a convenient position for inspection, the wheels which rotate the spindle are thrown out of gear. A pump for forcing the viscose through the spinning apparatus is likewise so mounted that it can be disengaged from the driving gear at will. The viscose passes from a supply pipe to the pump, is then forced through a filter carried by the frame on which the spindle is mounted, and afterwards travels through the rotating spindle to the nozzle, which is immersed in a coagulating bath. The thread, which is twisted by the rotation of the spindle and nozzle, is led over suitable guides to a winding reel which is provided with means for laying the thread as it is wound. This winding reel can also be put out of gear and replaced by another reel when required. All the driving means of the apparatus are geared so that they have the required relative speeds, which can be altered at will by change wheels. In the second of the present patents (No. 19,158), claim is not made for a rotatable nozzle.—P. F. C.

Artificial silk; Production of threads of —. Fürst Guido Donnersmarck'sche Kunstseiden und Acetatwerke. Fr. Pat. 398,424, Jan. 11, 1909.

THE twist may be given to the thread either during the process of spinning, or afterwards in a separate operation.

With viscose-silk it has been proposed to revolve the spinneret, so that twist would be imparted during coagulation, but in general, the coagulated thread is carried over a roller from which it falls into a rapidly rotating box. The degree of twist is dependent upon the relative speed of the roller and the box. These methods are not applicable, however, in the case of the cuprammonium and the nitrocellulose products, as the fibres obtained, do not appear to coagulate sufficiently rapidly to stand the mechanical strain. The twisting of the thread in a separate operation, has the advantage that the degree of twist can be more accurately controlled. The silk after coagulation is wound directly upon bobbins of small diameter; these are fixed in a winding machine and are rapidly revolved whilst the thread is reeled off into hanks.—F. M.

Volatile liquids, such as alcohol and ether, in the state of vapour diluted with air; Process for the recovery of — in the manufacture of artificial silk, smokeless powders and analogous operations. Soc. "L'Air Liquide" (Soc. anon. pour l'Etude et l'Exploit. des Proc. G. Claude) Fr. Pat. 397,791, Mar. 6, 1908.

THE recovery of the alcohol and ether present in the atmosphere of factories in which the manufacture of artificial silk (from collodion), smokeless powder, etc., is carried on, is not easy, owing to the high degree to which the vapours are diluted with air. In the present process the mixture of vapour and air is compressed and cooled and passed through an apparatus in which progressive refrigeration is possible. The compressed and cooled mixed gases are further cooled by permitting them to expand, and are then used as cooling agents for a further quantity of the compressed gases. By this arrangement very low temperatures may be reached, but it is essential that the temperature should not be such as would cause the separated liquids to freeze and block the apparatus.—F. M.

Bleaching wool; Apparatus for removing grease from, and —. D. Bouchat, Verviers, Belgium. Eng. Pat. 3196 Feb. 9, 1909.

THE wool is fed into the long arm of an inverted siphon, together with the liquid with which it is to be treated. It passes down the pipe, and is forced by the weight of the material behind it along the horizontal portion of the siphon, and up the short arm, from which it is delivered to squeezing rollers. In its passage through the siphon, it is first thoroughly impregnated, and then, by the pressure in the lower arm, it is partially freed from the impregnating liquid, which flows from perforations in the short arm of the siphon into a tank, from which it is pumped to the top of the entry pipe.—F. M.

Alkali peroxides in a soapy material; Package for the preservation of — [for bleaching]. E. Herrmann. Fr. Pat. 398,418, Jan. 12, 1909. Under Int. Conv., Jan. 12 and July 17, 1908.

THE alkali peroxide is packed in a closed vessel which is itself embedded in powdered material of a soapy character, contained in an outer package. When this outer package is opened and the contents emptied into a boiler used for washing, the inner package, which is sealed by a layer of some easily fusible material, such as a mixture of stearic acid and oleine, sinks, and opens automatically beneath the surface of the warm water. Hydrogen peroxide is formed, and caustic soda, which is rendered harmless, partly by the stearic acid and partly by sodium bicarbonate which may form an ingredient in the outer package. The ends of the inner cylinder may be closed by loose caps, held in position by an annular layer of the fusible material, so as to open very readily; or, the wall may consist of a spiral of iron wire made into a cylinder by tinning, and, instead of opening at the ends, a segment, running the length of its surface, may be closed by a layer of fusible material, the rest being tinned. It is claimed that less oxygen is wasted than with existing modes of packing, since decomposition takes place at a lower temperature (40°—45° C.) and beneath the surface of the water; there is also less danger of explosion.—F. SODX.

yeing, bleaching, etc.; Apparatus for —. A. W. Thompson, Manchester, N.H. U.S. Pat. 926,782, July 6, 1909.

HE apparatus comprises a vat, and a compression plate cover for the material. The cover is held in position by "dogs" detachably mounted on the same and extending radially over the edges of the vat. The extensions of the threaded vertical rods fixed to the exterior of the vat, and the "dogs" are then pressed down by means of weights.—F. M.

yeing machine. J. Richardson and J. F. Neef, Philadelphia. U.S. Pat. 927,599, July 13, 1909.

an open dye-vessel, a vertical shaft carries two sets of dial arms, the upper set being fixed, whilst the lower set is capable of being adjusted at any suitable distance from it. The arms of the two sets serve to carry the hanks in a stretched condition, and means are provided whereby they may be revolved upon their own axes. Loose material, perforated drums are carried vertically between the upper and lower arms, and the material is dyed therein.—F. M.

ool; Apparatus for supplying liquid to —. W. J. Murray, Bristol, Pa. U.S. Pat. 927,998, July 13, 1909.

HE apparatus is combined with a gill-box and consists of a liquid supply tank and a series of cocks or faucets opening into a trough-like spreader. The walls of the trough are parallel and close together, so that the viscosity of the liquid will prevent a too rapid discharge through the narrow slit which extends longitudinally along the bottom of the trough. The wool is carried on a belt beneath the opening and takes up the regulated supply of liquid, means being described whereby the cocks are opened and closed simultaneously with the starting or stopping of the machine.—F. M.

rn dyeing machine. C. Corron. Fr. Pat. 397,798, Mar. 7, 1908.

are attached, and revolve excentrically. The driving is effected by means of bevelled wheels, 9, 9', working through a worm gearing on the driving shaft, 5. By means of a change motion which is described, the direction of rotation of the driving shaft is periodically reversed, but at unequal intervals, so that the same portions of the hank are not always out of the liquor at the "change over."—F. M.

Weighting, dyeing or otherwise treating silk; Machine for — at various temperatures. C. Lump et Cie. Fr. Pat. 398,238, Mar. 18, 1908.

IN Fr. Pat. 383,947 of 1907 (this J., 1908, 445), a centrifugal dyeing machine is described, which however suffers from the defect that the spindle seat of the cage cannot be cooled and, when hot dye-liquors are in use, becomes overheated. In the case of an "overdriven" machine, the boss is now made hollow, and cold water is circulated through it to keep it cool, and in the case of an "underdriven" machine, the spindle bearings are hollow and are cooled in the same way. The silk is wound on bobbins which are placed on perforated tubes fitting into holes in the side of the cage, and the latter may be slowly or rapidly revolved by means of suitable gearing.—F. M.

Rolls for use in printing, paper making, textile and kindred arts. H. Brubaker, York, Pa., and H. D. Hershey, Columbia, U.S.A. Eng. Pat. 21,096, Oct. 6, 1908.

THE roll, 10 (see Fig.), is made up of a number of longitudinal wooden sections, 11. The lower corners of the

machine is especially useful in the dyeing of small lots of yarn, as the arms, 4, 4', upon which the hanks are supported may be revolved and manipulated quite independently of each other. These arms are raised and lowered by means of hydraulic rams, to which they

are attached, and revolve excentrically. The driving is effected by means of bevelled wheels, 9, 9', working through a worm gearing on the driving shaft, 5. By means of a change motion which is described, the direction of rotation of the driving shaft is periodically reversed, but at unequal intervals, so that the same portions of the hank are not always out of the liquor at the "change over."—F. M.

longitudinal keys, 19, arranged at intervals upon its surface. These keys, which are detachable from the metal tube, correspond in length and shape with the recesses, 14, of the sections, 11. A supporting ring, 21, provided with a keyway, 24, is arranged in each end of the tube, 20. When the roll is to be attached to a source of power, the end of a power shaft is inserted into these rings and is held therein by means of a key driven into the slot, 24.—P. F. C.

Printing process [for tri- and tetrabromindigo]. Farbenfabriken vorm. F. Bayer und Co. Fr. Pat. 398,571, Jan. 16, 1909. Under Int. Conv., May 30, 1908.

Owing probably to the great solubility of the leuco-derivatives of tri- and tetrabromindigo, these dyestuffs when printed in the same way as indigo, do not yield such full shades as would be expected. This objection is overcome, by incorporating with the printing mixture salts of the higher fatty acids, or organic sulphonic acids such as phenolsulphonic acid, benzylanilinesulphonic acid or naphthylaminesulphonic acid, etc.—F. M.

Skins; Machine for the "carroting" of— L. Beaulieu. Fr. Pat. 397,904, Dec. 16, 1908.

In the "carroting" of skins with mercury nitrate solution, it is desirable to impregnate the hair or fur with the reagent, without wetting the skin itself. In the present machine, the skin is passed between a pair of rollers provided with deep longitudinal grooves, the corrugations of the upper roller being roughened, with the object of raising the hair or fur. The skin then glides over an inclined table, provided with longitudinal channels, and below a rotating brush which is supplied with just sufficient of the mercury nitrate solution to impregnate the hair or fur. The skin is then passed between a second pair of grooved rollers and under a second rotating brush, which serves to distribute uniformly the mercury solution. The longitudinal channels of the supporting table are disposed quite close together, so that the area of contact of skin and table is as small as possible, and hence the danger of the flesh side of the skin becoming wetted with the mercury solution is reduced to a minimum.—A. S.

Linen; Process for the treatment of laundry— J. Paschka, Steglitz, and A. Koch, Berlin, Eng. Pat. 27,800, Dec. 21, 1908.

The linen after being washed and ironed, is coated with a solution of water-glass and then dried. When soiled, the treated linen can be cleaned by wiping it with a wet cloth. An addition of barium chloride to the solution of water-glass increases the suppleness of the prepared linen.—P. F. C.

Proofing of jute, hemp, linen, wool and other fibres. M. J. C. F. R. Lainville. Fr. Pat. 398,502, Jan. 4, 1909.

The process is intended specially for the "tannage" of fibres, woven, for instance, into a form suitable for sandals. The material is impregnated with a hot solution of gelatin, glue, gum, etc., in water containing glycerin, and is then dried. It is afterwards placed in a cold solution containing potassium bichromate, chrome alum, chromium tannate, tannin and formaldehyde, and again dried in a stove and, exposed to light, in the air.—F. M.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Nitric acid from the air; Manufacture of— in Austria. F. Russ. Zeits. f. Elektrochemie, 1909, 15, 544—548.

The process for obtaining nitric acid from the air, devised by H. and G. Pauling, is being worked by the Salpetersäure-Ind. Ges., at Patsch, near Innsbruck, in Austria. An arc is generated at the lowest point of two electrodes, set in a vertical plane at a considerable angle to each other, by a high-tension alternating current. The arc travels upwards between the electrodes until it attains a length of about

1 metre, to begin again at the bottom at the next half period of the current. A current of air is passed upward and fan-wise between the electrodes, and is deflected and cooled in the upper portion of the arc-zone by a horizontal current of "circulating" air which has already passed through the system; the velocity of this circulating air is less than that of the main supply. In order to start the arc readily, and yet not to oppose too great a resistance to the air, two subsidiary horizontal electrodes, consisting of thin strips of metal, are placed close together at the lowest point of the main electrodes; the current passes between the subsidiary electrodes at first, and then travels upwards as described, between the main electrodes. The latter are of iron, and are water-cooled; they last for 200 hours, the subsidiary electrodes being less durable. Lately, a special current of higher voltage than the main current has been used to start the arcs. Two sets of electrodes are combined in series by a special arrangement of wiring within each furnace; each furnace takes 40 kilowatts at 4000 volts, and deals with 600 cb. metres of air (exclusive of the "circulating" air) per hour, producing 60 grms. of nitric acid (HNO_3) per kilowatt-hour. The gases leave the furnace with a concentration of 1 per cent. of nitrogen oxides. A series of absorption towers, produce nitric acid of 35—40 per cent. strength, which concentrated to 60 per cent. by the heat of the gases sodium nitrite is also produced in a special plant. The factory at Patsch has 24 furnaces at work, using about 15,000 h.p. Two other factories, each with a capacity of 10,000 h.p., are in course of erection, one in the south of France, the other in the north of Italy.—A. G. L.

Acetic acid in Italy. Bd. of Tr. J., Aug. 12, 1909. [T.R.]

THE internal tax on the production of pure acetic acid and on the rectification of impure acetic acid is modified as shown in the subjoined statement:—

Classification.	Rates of the internal tax	
	As fixed by Law of 15th July, 1906.	As now fixed
	Lire etc. per 100 kilograms.	Lire etc. per 100 kilograms.
Acetic acid, pure, containing in anhydrous acetic acid:—		
10 % or less	15 00	15 00
More than 10 and less than 30 % ..	90 00	51 00
30 % or more, but less than 50 % ..		90 00
50 % .. " " 70 % ..		126 00
70 % .. " " 90 % ..	180 00	162 00
90 % or more		180 00

It should be noted that pure acetic acid imported into Italy is subject to the internal tax in addition to the Customs duty.

Sulphates; Formation of certain double— Barr. Compt. rend., 1909, 149, 292—295.

A DOUBLE sulphate of strontium and potassium $\text{K}_2\text{SO}_4\cdot\text{SrSO}_4$, is obtained by mixing solutions of the respective sulphates. It is the only double salt formed at temperatures between 0° and 100° C. The double sulphate of strontium and ammonium, $\text{SrSO}_4\cdot(\text{NH}_4)_2\text{SO}_4$, is a white crystalline salt, which is only stable in the presence of large quantities of ammonium sulphate. A double sulphate of lead and potassium, $\text{PbSO}_4\cdot\text{K}_2\text{SO}_4$, is produced by contact of lead sulphate with a solution of potassium sulphate, or by precipitation from a solution of lead acetate or nitrate. It is decomposed by water. The double sulphate of lead and ammonium, $\text{PbSO}_4\cdot(\text{NH}_4)_2\text{SO}_4$, is also decomposed by water, and to insure stability the solution must contain considerable quantities of ammonium sulphate. The author has been unable to prepare a double sulphate of strontium and sodium, or of lead and sodium.—C. A. M.

Silicates; Determination of alkalis in— G. Starck. Z. anal. chem., 1909, 48, 415—428.

THE present paper deals more especially with the determination of potassium and sodium in silicates when the

atter have been decomposed by means of hydrofluoric and sulphuric acids. It is shown that the resulting alkali sulphates may be converted into their corresponding chlorides by the addition of barium chloride, and the determination of the potassium may then be carried out directly without removing the excess of barium chloride. Methyl alcohol is employed for washing the potassium-platinum chloride precipitate, barium chloride and sodium-platinum chloride being soluble in this alcohol. The details of the method are as follows: The residue consisting of the mixed alkali sulphates is weighed, dissolved in water and transferred to a measuring flask of such capacity that, when the flask is filled to the mark, the solution shall be from 0.015 to 0.030-N., assuming all the alkali to be that of sodium. Sufficient hydrochloric acid is added to make the acidity of the solution approximately $N/10$, the mixture is boiled, and barium chloride solution is added drop by drop: the quantity of barium chloride employed, is calculated from the weight of the mixed sulphates, taking the latter to be all sodium salt. After cooling, the solution is diluted to the mark, filtered, and an aliquot portion of the filtrate is evaporated to dryness, after the addition of platinum chloride solution. The residue is moistened with water, and allowed to dry at the ordinary temperature, and then treated with small successive quantities of 80 per cent. methyl alcohol. The alcoholic washings are poured through a weighed asbestos filter on to which the precipitate is also brought and washed with the alcohol until the washings are colourless. After being dried at 130°C ., the filter and precipitate are weighed. If desired, the weighed precipitate may be dissolved, and the solution tested for barium, a correction being made if any be found.—W. P. S.

Hydrogen peroxide; Determination of acids in — by titration. O. Lüning. Z. angew. Chem., 1909, 22, 1549—1550.

ACCORDING to Endemann (this J., 1909, 473), the quantity of free acids in hydrogen peroxide cannot be determined correctly by titration in the cold, the higher value obtained by boiling with excess of alkali and then titrating back with acid, being the true one. The author has made experiments with pure hydrogen peroxide to which different quantities of sulphuric and hydrochloric acids were added, and found, on the contrary, that correct results are obtained by titration in the cold, the higher results obtained by Endemann's method being inaccurate.—A. S.

Phosphorus; Allotropic states of —. P. Jolibois. Compt. rend., 1909, 149, 287—289.

By fractional decantation with water, red phosphorus is separated into coarse granules of a deep violet colour, and fine yellowish-red particles which will remain suspended in the water for several months. A simple titration will convert one kind into the other, and the author therefore suggests that the colour of phosphorus, so long regarded as characteristic of its allotropic form, may be solely due to the fineness of the particles. The colloidal phosphorus obtained by suspending the finest particles in water cannot be regarded as a distinct allotropic form. On heating red phosphorus in sealed tubes to 200°C . in the absence of air, the colour changes from violet to red, and the specific gravity rises from 2.18 to 2.37. No further change in the density occurred after continuing the heating for $2\frac{1}{2}$ hours at 450°C ., and for $\frac{1}{2}$ hours at 600°C . Hence the specific gravity is not, as commonly believed, a function of the temperature to which the phosphorus has been heated. Commercial red phosphorus, obtained by heating white phosphorus, is in an unstable condition, and even at the temperature at which it is prepared (280°C .) the catalytic action of a trace of iodine is sufficient to transform it into the stable modification, to which the author gives the name of *monomorphic phosphorus*. Incomplete conversion of red phosphorus into this stable form results in the formation of a purple-coloured product, which microscopical examination indicates to be in a state of solid solution, and not to consist of particles of the two varieties in juxtaposition. On fusing red phosphorus at 725°C ., a modification of violet colour with a sp. gr. of 2.27 was obtained. On

cooling the tube suddenly, this product remained unaltered in appearance and density—a result contrary to the experience of Chapman (this J., 1899, 518), who by this means obtained white phosphorus.—C. A. M.

Hydrogen phosphides, P_2H_6 and P_2H_2 ; Preparation and properties of the solid —, and action of liquefied ammonia on them. A. Stock, W. Böttcher, and W. Lenger. Ber., 1909, 42, 2839—2863.

EXISTING methods for the preparation of the solid yellow hydrogen phosphide, P_{12}H_6 , are faulty. The authors found that the best method is one based on the fact that the spontaneously inflammable hydrogen phosphide decomposes, with separation of the solid yellow phosphide, when it comes in contact with granulated calcium chloride. Calcium phosphide is introduced into a flask containing warm water, and the gas evolved is led first through a tube in which the greater part of its moisture is deposited, then through three tall tubes packed with the granulated calcium chloride, and finally through a wash-bottle containing concentrated hydrochloric acid. The calcium chloride then becomes coated with solid yellow hydrogen phosphide. It is introduced, in small portions at a time, into dilute hydrochloric acid, cooled to 0°C ., the mixture being vigorously agitated, and protected from direct sunlight. When the calcium chloride has dissolved, the solution is siphoned off, and the phosphide is washed with ice-cold water, alcohol, and anhydrous ether, and dried over sulphuric acid and phosphorus pentoxide in a vacuum exsiccator in an ice-chest. The pure freshly-prepared phosphide is a canary-yellow, odourless, amorphous powder, of sp. gr. 1.83 at 19°C ., neutral to litmus paper: when kept in the air, it soon evolves phosphine and becomes acid. It may be preserved unaltered over sulphuric acid or phosphorus pentoxide in the dark, but rapidly decomposes when exposed to the light. When it is heated *in vacuo*, evolution of gas begins at 60°C ., ceases at about 200°C ., and then begins again at about 260°C ., continuing until the phosphide is almost entirely converted into red phosphorus, phosphine, and hydrogen. The gas evolved, at first consists of pure phosphine, and the orange-coloured residue left, is a new phosphide of the composition, P_6H_2 , and sp. gr. 1.95 at 16°C . This new phosphide is best prepared by heating the yellow phosphide at 175°C . *in vacuo* or in a current of carbon dioxide until gas is no longer evolved. It is almost identical with the yellow phosphide in its chemical properties, but differs from the latter in its behaviour with liquefied ammonia. When the yellow phosphide is treated with liquefied ammonia, phosphine is evolved and a red colloidal solution of the orange-coloured phosphide is produced. When this solution, which is also produced when the orange-coloured phosphide is treated directly with liquefied ammonia, is evaporated, a black compound of salt-like character, and of a composition varying between the limits, $\text{P}_6\text{H}_2\cdot\text{NH}_3$ and $(\text{P}_6\text{H}_2)_2\cdot\text{NH}_3$, is produced. The orange-coloured phosphide can be regenerated from the black salts by heating *in vacuo* or by treatment with acids.—A. S.

Volumetric determination of lead, and of sulphuric acid in sulphates. Oddo and Beretta. See XXIII.

Ammonium sulphate in Japan. For. Office Ann. Series, 1909, [T.R.]

THE British Consul at Kobe, Japan, states that in ammonium sulphate of British production there has been an increase of over £330,000 on the last five years' average and of £71,000 over last year's import. Nevertheless, what with the over-production of fertilizers by the Osaka manufacturers, and the refusal of the farmers to purchase, the trade was in a deplorable condition. As in many other lines, fertiliser factories had sprung up in such numbers as to make it impossible for profits to be reaped.

Phosphates in the Palm Islands (Germany). Bd. of Tr. J., Aug. 5, 1909, [T.R.]

UNDER the style of the German Phosphate Company an association has been formed at Bremen with a capital of

£225,000 to work the phosphate stocks in the Island of Angaur (Palem Islands). The German Government will share in the profits of the company.

PATENTS.

Ferric sulphate; Manufacture of — and making same up with more or less waste products to produce cakes or slabs [for sewage treatment]. W. Pochin and J. H. Richardson, Salford. Eng. Pats. 15,239, July 18, 1908, and 17,976, Aug. 27, 1908.

THE waste hydrated ferric oxide, obtained in the extraction of alumina from bauxite or other aluminous ores, is treated with sulphuric acid and the solution evaporated to 160° T. Waste silicious material, or sand, is added to the above solution to act as absorbent, and the mixture is moulded into blocks, which then contain about 10 to 15 per cent. of waste silica, and are suitable for sewage purification. The faces of the blocks are preferably dressed with a coating of lime, cement, or clay, to facilitate handling and storage. Instead of waste silica, the aluminium sulphate compound, described in Eng. Pat. 25,227 of 1907 (this J., 1908, 898) may be used as carrier for the ferric sulphate, in which case the facing treatment of the slabs is probably unnecessary.—O. R.

Abrasive and polishing material [magnesium carbonate]. J. Leese, Manchester. Eng. Pat. 4819, Feb. 27, 1909.

POWDERED normal magnesium carbonate (magnesite), either by itself, or as a paste mixed with water or certain solutions, or pressed into blocks with wax or soap, is claimed as a new and improved abrasive and polishing material for metals.—O. R.

Alkali chlorides; Electrolysis of —. J. Billitzer, Vienna. U.S. Pat. 928,734, July 20, 1909.

THE cell is arranged so that part of the cathode product forms a layer containing alkali, separated from the electrolyte below it by a diaphragm, and this alkali is continuously run off at the level of the diaphragm, fresh solution being introduced below the diaphragm.—A. T. L.

Dolomites; Process of treating —. Soc. Minière de L'Hérault. Fr. Pat. 398,668, Jan. 21, 1909.

THE dolomite is heated to about 300° C., in order to get rid of organic matter, and then more strongly in retorts, so as to obtain a mixture of lime and magnesia. This is allowed to cool in closed receivers and is either utilised directly or treated with a solution of sugar which dissolves the lime, leaving the magnesia insoluble, and the calcium sacrate is then decomposed by passing a current of carbon dioxide, obtained in the process, through the solution, so as to precipitate the calcium as carbonate and regenerate the sugar solution. The process provides a means of utilising dolomites containing a comparatively small proportion of magnesium carbonate.—F. SODS.

Calcium carbonate; Chemical and mechanical process for the treatment of minerals containing —. F. Gisbert Buendia. Fr. Pat. 398,699, Oct. 1, 1908. Under Int. Conv., Oct. 1, 1907.

THE calcareous mineral is broken up into pieces of uniform size, which are calcined in a fixed kiln, at a moderate temperature. The calcined mineral is then treated with steam or water, which converts the lime formed into finely-divided calcium hydroxide, and leaves the other constituents of the mineral unattacked. The mass is next sifted through two sieves, the first with meshes of 5 mm., and the second with meshes of 1½ mm. The coarsest fraction so obtained is tested for calcium carbonate, and reburnt, if necessary. The intermediate fraction is treated with more water, and the calcium hydroxide obtained, added to the finest fraction, which contains the bulk of the lime. This last fraction is further purified by levigation, an apparatus being used in which the solid in descending through a zig-zag passage meets two upward currents of water, one a steady current, the other an intermittent current, which communicates a series of pulsations to the whole body of water. The finely-divided and specifically light calcium hydroxide is

discharged from this apparatus through an opening near the top, whilst the heavier minerals are discharged from time to time at the bottom. The process is designed to yield a pure lime, and is also adapted to the treatment of rocks containing calcium carbonate mixed with a little copper carbonate, etc.—A. G. L.

Nitrites; Transformation of — into nitrates. Badiscl Anilin und Soda Fabrik. Fr. Pat. 398,738, Jan. 23, 1909. Under Int. Conv., July 6, 1908.

ALKALINE-EARTH nitrites or mixtures containing them such as those obtained by using alkaline-earth bases as absorbents of nitrous gases, are treated at about 300° C. with the higher oxides of nitrogen, preferably in the presence of air or oxygen; they are thus completely converted into nitrates, and nitric oxide is also produced which acts as a carrier of oxygen to a further quantity of nitrite.—F. SODS.

Gases [oxygen] from solids; Obtaining —. C. Ridley London. Eng. Pat. 15,000, July 15, 1908.

THE claim is for a process of obtaining gases from solid in a continuous manner, applicable to obtaining oxygen from sodium permanganate, lead oxide, etc. The material is fed into a hopper and passes between a pair of rollers; it is then conveyed by screw conveyors first horizontally and then vertically, and is dropped into a vertical retort where it is heated with a current of steam or hot air, and the gas is driven out. The spent solid material is discharged from the bottom of the retort, and after reabsorbing oxygen from the air, is passed through the apparatus again.—W. H. C.

Air; Process for the separation of — into its elements [oxygen and nitrogen]. Soc. l'Air Liquide (Soc. Anon. pour l'Etude et l'Exploit. des Procédés G. Claude). Fr. Pat. 398,580, Mar. 26, 1908.

THE process consists essentially in submitting liquid oxygen, vaporised by the liquefaction of air, to three successive combined rectifications, effected (1), with the liquid, rich in oxygen, resulting from the partial liquefaction of the air in reflux tubes; (2), with the nearly pure liquid nitrogen, obtained by liquefying the more volatile remainder of the air; and (3), with the pure nitrogen, resulting at the top of the rectifying column and liquefied by refrigeration by means of evaporating oxygen. By way of example, an apparatus is described, consisting of a boiler, containing liquid oxygen and surmounted by a rectifying column. A double system of vertical tubes is immersed in the liquid, into one set of which is admitted purified air, compressed and cooled; this is partially liquefied in ascending the tubes, the liquid collecting below containing practically all the oxygen; the remaining air then descends the other set of tubes and nearly pure liquid nitrogen collects at the bottom. The oxygen, vaporised in the boiler by the condensing air, meets, as reflux liquid, in the lowest portion of the column, the air liquefied in the first set of tubes, containing about 48 per cent. of oxygen, and a gradual exchange of oxygen for nitrogen in the ascending gas takes place; the middle portion of the rectifying column is supplied with the more volatile portion of the liquefied air as reflux liquid, and this effects the removal of all but about 3 per cent. of the oxygen; in the highest section of the column, the reflux liquid is a portion of the pure nitrogen resulting from the rectification, which is liquefied in a system of tubes in a second boiler placed above the rectifier, by the evaporation of contained oxygen, at a lower pressure than the nitrogen. Air is separated by the process into very pure nitrogen and practically pure oxygen.—F. SODS.

Alkali peroxides [for bleaching]. Fr. Pat. 398,448. See V.

VIII.—GLASS, POTTERY, AND ENAMELS.

Clays; The colloidal substances in —. P. Rohland Z. Elektrochem., 1909, 15, 540–542.

THE degree to which clays can be “liquefied” by addition of alkalis, etc., depends largely on the amount of organic

natter they contain. Pure white kaolins are but little affected by such additions, whilst the dark coloured, highly plastic clays are readily "liquefied." A. Lotternoser has recently stated that lime-water is unsuitable for his purpose, but the author finds that a number of clays from Saxony, which are rich in organic matter, are readily liquefied by this reagent.—A. G. L.

Iron in pottery materials; Colorimetric determination of —. Hadank. *Sprechsaal*, 1909, 42, 445.

The colorimetric estimation of iron by ammonium thiocyanate is said to be quicker and more accurate than titration with permanganate. The author conducts the process in a König apparatus, consisting of a six-sided rotating prism to which are attached six strips of varying shades of red. Next to this is a cylinder containing the solution of the sample in hydrochloric acid to which has been added a pinch of chlorate. The matching of colours is then carried out in the usual way. The process is useful for estimating iron in cement, sand, tufa, manganese ore, sodium sulphate, clay and similar materials.—H. H. S.

PATENT.

China clay; Purification of —. A. G. Salamon, London, C. J. Grace, Steyning, and The Exploration Co., Ltd., London. Eng. Pat. 21,260, Oct. 8, 1908.

To the china clay emulsion, which is taken from the depositing vessels or channels, chlorine water and a small quantity of sulphuric acid are added, the mixture is pumped through filter-press, the resulting cake is washed as free as possible from chlorine and sulphuric acid, and finally dried if desired. It is claimed that by this procedure a clay of second quality can be converted into one of first quality. —O. R.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Cement industry of Germany. Bd. of Tr. J., Aug. 5, 1909. [T.R.]

The expectations of the German cement industry at the commencement of 1908 were not realised. In consequence of the financial crisis, large stocks accumulated during the summer at the cement factories. The latter sought relief in the export market, with the result that prices fell nearly 5 per cent.; whereupon several of the syndicates disposed of their stocks. The year was nevertheless regarded by the German cement works as good, because home prices, regulated by agreement between the syndicates, ensured a good profit. These agreements have been renewed for 1909, and the German cement works are now trying to raise the export prices. It is said also that efforts have been made with some success to secure the adhesion of the British and Belgian cement industries, and it is anticipated that it will be possible to form international agreements for the regulation of export prices. The total output of cement in Germany in 1908 is estimated to have been as follows:—

	Casks of 150 kilos.
Portland cement	23,000,000
"Iron" Portland and Slag	2,250,000
Roman	650,000
Total	25,900,000

The factories are, however, said to be capable of turning out nearly twice this quantity. Of the total number of cement factories in Germany, viz. 142, 97 manufacture only Portland cement.

PATENTS.

Basic fire-brick lining. S. B. Newberry, Baybridge, Ohio. U.S. Pat. 927,585, July 13, 1909.

The patent relates to the manufacture of refractory or basic bricks from hydraulic cement clinker, alone, or in admixture with an alkaline-earth. The clinker is used in granulated form, the bricks being made by moulding in the ordinary manner.—W. E. F. P.

Wood; Drying and treating —. C. Gillet, sen. Fr. Pat. 397,786, Mar. 6, 1908.

WOOD, preferably previously dried, is immersed in a bath of drying-oil, preferably boiled linseed oil, heated to a temperature of 100°–110° C. Planks 3–4 cm. in thickness are immersed in the oil for 24 hours, and are ready for use in 15–30 days.—A. G. L.

Agglomeration or hardening of powdered substances. Fr. Pat. 398,615. See X.

X.—METALS AND METALLURGY.

Ferro-manganese in the blast-furnace. J. Jakobi. *Stahl u. Eisen*, 1909, 29, 1119–1120.

The paper contains an account of the production of ferro-manganese in a South Russian blast-furnace, the trials extending over nine days. Two samples of ore were employed; both of these were rich in manganese (51.6 and 53.5 per cent.) and contained but little silica (7.80 and 6.20 per cent.). The contents of phosphorus were however rather high, so that, of the second ore (Ore II.), only small quantities could be employed. Using a charge as follows: Ore I., 5875 kilos.; Ore II., 1469 kilos.; hæmatite, 163 kilos.; limestone, 2448 kilos.; coke, 8160 kilos, 70 per cent. of the manganese was obtained in the ferro-manganese, 10 per cent. in the slag, and 20 per cent. was lost by volatilisation, etc. In the nine days' working, giving a total production of 718,896 kilos. of ferro-manganese (containing 78 to 83 per cent. of manganese), an average loss of 23.1 per cent. of manganese was shown, the slag, containing on an average 6.6 per cent. of manganese. The consumption of coke, extending over this time, amounted to 2272 kilos. per metric ton of ferro-manganese produced. In the production of the alloy, ore and coke were well moistened and the temperature of the mouth gases was kept as low as possible and never greater than 200° C. The author emphasises the importance of having a high air-blast temperature and in this particular his opinion is opposed to that of Stöckmann, who has stated that a temperature of 420° C. is quite sufficient.—C. A. W.

Iron and steel; The elastic limits of — under cyclical variations of stress. L. Bairstow. *Proc. Roy. Soc.*, 1909, A., 82, 483–485.

The results of the author's experiments are in harmony with the theory advanced by Bauschinger in 1886 in explanation of fatigue. It is shown that, between certain limits, and after a sufficient number of repetitions, iron or steel is capable of adjusting itself to cyclically applied variations of stress, the specimen becoming perfectly elastic throughout the whole cycle—when the adjustment is complete—without the occurrence of fatigue. A change of length, corresponding to that observed in an ordinary tensile test when the yield stress is exceeded, occurs in the specimen during the adjustment of the elastic limits to a given cycle of stress; but in the latter case the elongation is obtained even when the maximum stress in the cycle is less than the static yield stress, the increase in the elastic limits being greatest in specimens showing the highest elongations. Below the static yield point, iron and steel appear to be capable of maintaining their initial condition for a considerable time against cyclical variations of stress which ultimately produce a considerable change of length.—W. E. F. P.

Calcium sulphate; Behaviour of — at elevated temperatures with some fluxes. H. O. Hofman and W. Mostowitsch. *Trans. Amer. Inst. Min. Eng.*, 1909, 621—622.

DURING the testing of the action of different substances on calcium sulphate at high temperatures (see this J., 1909, 246), it was stated that no appreciable alteration was noticed when ferric oxide was heated alone in a current of dry air to 1500° C., but that, in the presence of calcium sulphate, complete decomposition took place at 1250° C. with the formation of calcium ferrite.

The author has since found that when using larger quantities of ferric oxide and heating alone for longer periods, decomposition commences at 1375° C. with the formation of some magnetic oxide.—F. R.

Heavy spar (barium sulphate); Behaviour of — at high temperatures and its reactions with some substances used in metallurgy. W. Mostowitsch. *Metallurgie*, 1909, 6, 450—467.

PURE barium sulphate can be heated in pure, dry air for 15—30 minutes at 1400° C. without decomposition; at 1500° it begins to dissociate to a small extent. When heated rapidly, it melts at 1580°, with partial decomposition into barium oxide, sulphur dioxide, and oxygen. Barium sulphate is decomposed by both silica and ferric oxide at 1000°. The sesqui-, bi-, and tri-silicate mixture sinter at 1350°, and fuse at 1400° C.; the melted mass contains undecomposed barium sulphate in solution. The degree of decomposition increases with the temperature and the proportion of silica present. The behaviour of mixtures of barium sulphate with one, two, and three molecular proportions of ferric oxide is similar, the sintering and melting-points being the same, but far more ferric oxide than silica is required to effect the same degree of decomposition; the ferrites formed, are thin liquids, solidifying to crystalline masses; they are capable of dissolving both barium sulphate and ferric oxide. The reduction of barium sulphate by carbon, begins at 600° and is practically complete at 800° C. With carbon monoxide, reduction begins at 650° and is nearly complete at 800° C. When heated to 1200° in an atmosphere of carbon monoxide, the barium sulphide formed loses a small proportion of its sulphur. The decomposition of barium sulphate into barium oxide, sulphur dioxide, and oxygen involves the absorption of a large quantity of heat (136,740 calories), and this may occasionally be useful in lowering the temperature of the slag in the converter treatment of lead and copper. Slags containing barium are very liquid, but specifically heavy. Such slags are able to dissolve iron from copper matte. When heated in a reducing atmosphere, barium sulphate is readily reduced to sulphide, which has a strong tendency to enter the matte; a matte containing 35 per cent. of barium has been obtained. Barium sulphide apparently tends to carry the noble metals into the matte.—A. G. L.

Mercury ores; Shortening the roasting period for —. W. B. Dennis. *Eng. and Min. J.*, 1909, 83, 112—116.

A FURNACE, designed by the author and constructed at Blackbutte, Oregon, is stated to have reduced the time previously required for roasting mercury sulphide ores (viz., 24 to 36 hours) to four hours, and to have resulted in a more complete roast with the consumption of less fuel. The furnace was designed in accordance with the principle that the speed at which heat will be absorbed by a substance is greater, the greater the difference between the temperature of the substance and that of the heating agent. It consists of a number of superimposed gas-fired hearths each with independent hot air- and gas-supplies so that the required temperatures may be maintained. The ore is fed in at the top and is dropped through from hearth to hearth by means of dumping grate-bars; it is moved successively into hotter zones, whilst still considerably below the temperature of that in which it was being heated, thus maintaining a "steep temperature slope."—F. R.

Boiling points of metals; Approximate determination of —. H. C. Greenwood. *Roy. Soc. Proc.*, 190 A 82, 396—408.

THE author recounts the difficulties which have attended previous attempts to obtain reliable data as to the boiling points of various metals, among which he names (1) the fact that many metals possess a high vapour tension at temperatures much below their actual boiling point; (2) errors arising from the conductivity of such vapour and from the presence of carbon in the metal. After trial of several methods the one eventually adopted was based on the employment of a vertical carbon tube resistance furnace, in which was suspended a long graphite crucible containing the metal under investigation. The depth of metal employed was usually about 30 mm. Temperature readings of the outer walls of the crucible were taken by means of a Wanner optical pyrometer, a side tube being provided exactly opposite the lower end of the crucible, and being so arranged that only the radiation from the crucible walls could fall on the pyrometer; the side tube was kept clear of vapours by a current of hydrogen. The measurements of the boiling points were carried out by slowly raising the temperature of the crucible and observing the surface of the metal from above through an absorbing glass. At first the surface remains perfectly still, but as the boiling point is approached a slight agitation is observed which soon becomes vigorous. In the case of most metals studied, the difference between the temperature indicated when a gentle agitation is first apparent and that at which the ebullition has become so violent that globules of metal are ejected, does not exceed 100° C. In order to decide whether the temperatures measured on the outer side of the crucible indicated with sufficient accuracy the actual temperature of the metal, similar experiments were conducted with an annular crucible heated from within, the outside temperatures being measured as before. Experiments made with lead proved a close agreement between the results obtained by the two methods.

For determination of the boiling point of metals which readily carburise, recourse was had to carbon crucibles "brasqued" with highly shrunk pure magnesia, special precautions being taken in their preparation to obviate cracking, to which they are very liable.

The following boiling points were determined by this method:—Aluminium, 1800°; antimony, 1440°; bismuth, 1420°; chromium, 2200°; copper, 2310°; iron, 2450°; lead, 1525°; magnesium, 1120°; manganese, 1900°; silver, 1955°; and tin, 2270° C.—R. C. P.

Iodometric determination of copper. Videgren. See XXII.

Lead poisoning and tinning. Extracts from Report by E. J. H. Lawes, June, 1909. (See this J., 1909, 797.)

IN their report for 1902, Dr. Legge (Medical Inspector) and Miss Anderson (Principal Lady Inspector) stated that they were struck at the extent of lead poisoning among the tinning operatives, and expressed their disagreement with a clause in the report of Mr. Gould's Lead Committee of 1893, to the effect that the health of the workpeople employed in the manufacture of any kind of hollow-ware was not much affected by their employment. They made careful inquiries into the causes of lead poisoning, and with the help of the Public Analyst of Wolverhampton reported tentatively that inhalation of lead dust was the chief cause, and that the amount of lead which might be absorbed by eating with unwashed hands was also sufficient to cause the symptoms. They considered that the processes of tinning were so different from those of enamelling that the subjects required separate treatment and promised a further inquiry and supplementary report upon the tinning industries.

G. E. Duckering made an important discovery, namely, the presence of lead chloride in the fumes given off from the tinned article, and though perhaps he goes rather far in saying that the danger is entirely due to the fumes, there is no doubt that the metallic lead dust and unwashed hands must now be regarded as inconsequential, compared with the danger of inhaling fumes con-

aining lead chloride whether in the form of vapour or dust, as lead chloride is very soluble in the human system."

The process of tinning.—"The making of 'tin plates' which are iron plates coated with tin—and the 'purchasing' of hollow-ware, both of which are different processes in which no lead is used, are not affected. The making of 'terne-plates' was also expressly exempted. A terne-plate is an iron plate coated with a mixture of tin and lead. They are mostly manufactured in South Wales. Owing to the difference of process and the chemical interactions which are not perfectly understood, this is a harmless industry and there is little or no evidence of lead poisoning in it. The iron plate after being cleaned in the pickling bath of dilute sulphuric acid, is washed in water and there are no chlorides brought into contact with the tinning metal; there is no excess of tinning metal on the surface of the iron plate, which is not wiped by hand, and no injurious vapours can be discovered. I need not dwell at length upon this process, which is explained and discussed in Mr. Duckering's report already referred to. The process of common tinning is interesting, and here again the chemical changes do not seem to be very well understood, although I have no doubt that Mr. Duckering's experiments have done much to explain them. The process is much the same in all branches of the industry. The article to be tinned, whether a sheet of copper or nickel or an iron hame for a horse collar or a cooking utensil, is plunged into a pickling bath containing dilute solution of hydrochloric acid: this is for the purpose of cleansing it from oxides which have collected upon its surface. It is then dipped into another bath containing 'killed acid,' which is hydrochloric acid imperfectly neutralised with metallic zinc, and is really a weak acid solution of zinc chloride containing a good deal of free hydrochloric acid. The result of the action of this acid upon an iron surface is to produce ferrous chloride. What the action of the acid is upon a copper or nickel sheet does not seem to be fully explained, but either zinc chloride or hydrochloric acid remains on the surface of the metal. The article is next put into the bath of molten metal, which contains a mixture of tin and lead of varying proportions according to the quality of article required. In some cases there is as much as 90 per cent. of lead, in others only about 15 or 20 per cent. of lead. Upon inquiry, during my several visits to factories, I found the amount of lead usually varied from 40 to 75 per cent. This bath is known as the 'dipping bath' and this part of the process, as 'dipping.' Lead is very much cheaper than tin, but another fact which makes the mixture of the metals popular is that whereas lead melts at 330° C. and tin at 235° C., the mixture melts at a lower temperature than either, viz., 171° C. to 188° C., according to the proportions. This has an important bearing upon the question of wiping, as the higher the melting point the sooner the metal sets, and the more difficult it is to wipe an article such as a kettle, which takes some time to wipe thoroughly.

"After immersion in the 'killed acid' the article is dipped in the bath of molten metal. I am satisfied that it is at this point the danger of lead absorption commences. Strong steamy fumes are immediately given off, and whether there is lead in them at first or not (Mr. Duckering thinks not) there is no doubt that lead chloride is soon generated. Either the zinc chloride or hydrochloric acid upon the surface of the metal article acts upon the lead in the bath; chloride of lead is formed and probably vapourised by the heat of the bath. If there is a hood with an adequate draught over the bath, these fumes ought to go up the chimney, but as a matter of fact the hood and the draught are not usually adequate, and I have no doubt some of these fumes enter the air of the shop breathed by the dipper and his assistant. After being dipped in the bath of molten metal for about half a minute, the article is found to be coated with the tinning metal which adheres to its surface. The fumes cease to rise, at any rate in the same obvious quantity, but it must not be assumed that evolution of vapour of lead chloride has ceased; on the contrary,

according to the evidence, the molten metal continues to give off vapour until it is set. Hence the danger of wiping, which is the next process. When the tinned article is taken out of the dipping bath, it has to be wiped whilst still hot, before the metal hardens. This is done in different branches of the industry with different substances—either tow, straw or hay, but never with a rag or cloth—and the object is to make the surface smooth by removing the surplus metal, as more adheres than is required to tin it. This wiping is usually done in the open shop, rarely under a cover, and very rarely under an adequate draught, though improvements have recently been made by some firms in this direction. As the trade is at present carried on I regard the wiping as the most serious source of danger owing to the length of time it takes, during which lead vapour is given off; also to the fact that probably there is more lead chloride given off in the fumes from wiping than from dipping; there is no method at present of removing these fumes during the wiping process and the worker stoops, and is very close to the article he is wiping."

Factory and Workshop Act. Dangerous and unhealthy industries. Regulations, dated June 30, 1909, made by the Secretary of State for the tinning of metal hollow-ware, iron drums, and harness furniture. Statutory Rules and Orders, 1909, No. 720.

WHEREAS the coating of metal articles with a mixture of tin and lead, or lead alone, has been certified in pursuance of Section 79 of the Factory and Workshop Act, 1901, to be dangerous; I hereby in pursuance of the powers conferred on me by that Act make the following Regulations and direct that they shall apply to all factories and workshops where tinning is carried on in the manufacture of metal hollow-ware, iron drums, and harness furniture.

Provided that these Regulations shall not apply to:—

- (a) Any process in silver plating.
- (b) Any process in which a soldering iron is used.
- (c) Any other process if and so far as it is exempted by written certificate of the Chief Inspector of Factories, on the ground that he is satisfied that any of these Regulations are not required for the protection of the persons employed, by reason of the intermittency or infrequency of the tinning or other special circumstances.

Any such certificate of exemption shall be subject to the conditions therein prescribed and may be revoked at any time.

These Regulations shall come into force on October 1, 1909, except that Regulation 1 shall come into force on April 1, 1910.

Definitions.

In these Regulations:—

"Tinning" means the dipping and wiping of any metal in the process of coating it with a mixture of tin and lead or lead alone where hydrochloric acid or any salt of that acid is used.

"Mounting," "Denting" and "Scouring" mean the mounting, denting, and scouring of hollow-ware articles tinned on the outer surface.

"Surgeon" means the Certifying Factory Surgeon of the district or a duly qualified medical practitioner appointed by written certificate of the Chief Inspector of Factories, which appointment shall be subject to such conditions as may be specified in that certificate.

"Suspension" means suspension from employment in tinning by written certificate in the Health Register signed by the surgeon.

"Efficient draught" means localised ventilation effected by heat or mechanical means for the removal of fumes or dust so as to prevent them as far as practicable from escaping into the air of any room in which work is carried on.

No draught shall be deemed efficient which fails so to remove smoke generated at the point where such fumes or dust originate.

Duties.

It shall be the duty of the occupier to observe Part I. of these Regulations.

It shall be the duty of all persons employed to observe Part II. of these Regulations.

PART I.*Duties of Employers.*

1. No tinning shall be carried on except under an efficient draught.

The article to be tinned shall not be removed from such draught from the time when dipping is commenced until wiping is completed.

This Regulation shall not apply to the wiping of sheet metal 18 inches or more in length, where the person employed is wiping such sheet metal for his own use in some other process of his work.

2. No person under 16 years of age shall be employed in tinning.

3. The skimmings from the dipping bath shall not be removed from under the efficient draught until they have been placed in a covered receptacle. When removed they shall not be deposited in any room in which work is carried on.

4. The dust and refuse collected from the floor shall not be deposited in any room in which work is carried on.

5. A Health Register containing the names of all persons employed in tinning shall be kept in a form approved by the Chief Inspector of Factories.

6. Every person employed in tinning shall be examined by the surgeon once in every three months (or at such shorter or longer intervals as may be prescribed in writing by the Chief Inspector of Factories) on a day of which due notice shall be given to all concerned.

The surgeon shall have the power of suspension as regards all persons employed in tinning, and no such person after suspension shall be employed in tinning without written sanction from the surgeon entered in the Health Register.

7. There shall be provided for the use of all women employed in tinning:

(a) a cloak room, or other suitable place, separate from any room in which work is carried on, for clothing put off during working hours;

(b) aprons or other equivalent protection.

8. There shall be provided for the use of all persons employed in tinning, mounting, denting, or scouring, a room, separate from any room in which such work is carried on, where such persons may have meals, unless the works are closed during meal hours.

9. There shall be provided and maintained in a cleanly state and good repair for the use of all persons employed in tinning, mounting, denting, or scouring, a lavatory, under cover, with a sufficient supply of clean towels, renewed daily, and of soap and nail brushes, and with either:—

(a) A trough with a smooth impervious surface, fitted with a waste pipe without plug, and of such length as to allow at least two feet for every five persons, and having a constant supply of warm water from taps or jets above the troughs at intervals of not more than two feet; or,

(b) At least one lavatory basin for every five such persons, fitted with a waste pipe and plug, and having either a constant supply of hot and cold water or warm water laid on, or (if a constant supply of heated water be not reasonably practicable) a constant supply of cold water laid on, and a supply of hot water always at hand when required for use by persons employed.

PART II.*Duties of Persons Employed.*

10. Every person employed in tinning shall present himself at the appointed time for examination by the surgeon as provided in Regulation 6.

11. No person employed in tinning shall:—

(a) After suspension, work at tinning without written sanction from the surgeon entered in the Health Register; or

(b) Interfere in any way, without the concurrence of the occupier or manager, with the means and appliances provided for the removal of dust or fumes, and for the carrying out of these Regulations.

12. Every person employed in tinning, mounting, denting, or scouring shall wash the hands before partaking of food or leaving the premises.

13. No person employed in tinning, mounting, denting, or scouring shall keep or prepare or partake of any food or alcoholic drink in any room in which such work is carried on.

H. J. GLADSTONE,
One of His Majesty's Principal
Secretaries of State.

Home Office, Whitehall.
30th June, 1909.

Mineral production of Potosi, Bolivia, in 1907. Bd. of Tr. J., Aug. 5, 1909. [T.R.]

THE products of Potosi are essentially mineral, and form 44 per cent. of the total exports of Bolivia. The official figures for the production in 1907, which are the latest available, are as follows:—

	£
Tin	2,220,000
Silver	440,000
Copper	6,000
Bismuth	75,000

Russian manganese ore. Chem. and Drug., Aug. 7, 1909.

IN 1908 the manganese producers of the Caucasus, expected that exports would expand so soon as contracts from India should expire. When the time drew near, the trade went from bad to worse, so that a large number of producers at Tchiaturi were compelled to either shut down, or liquidate. Only two or three of the sounder firms were able to continue production. Prices of manganese ore at the mines in 1908 were 1½d. per 36 lb., as compared with 4d. to 4½d. when the industry was in a flourishing condition. The high transport rates charged by the State railways and Indian competition have brought about the present unhealthy condition. On the other hand, the Indian and Brazil manganese industries have steadily forged ahead in European markets and elsewhere, as the following figures relating to exports show:

Year.	Brazil.	British India.	Poti and Batoum.
	tons.	tons.	tons.
1902.....	157,295	144,037	478,421
1903.....	161,926	171,804	439,915
1904.....	208,260	154,880	453,109
1905.....	224,337	282,334	313,095
1906.....	201,500	310,446	494,506
1907.....	231,410	611,692	490,759
1908.....	—	—	371,760

Manganese ore in the United States. U.S. Geological Survey, 1909. [T.R.]

FEWER mines were in operation in 1908 than in 1907. Eleven mines produced 6144 long tons, nearly all of which was used for chemical purposes. The production of manganiferous zinc residuum from New Jersey zinc ores amounted in 1908 to 110,225 long tons, an amount greater than in any preceding year. During 1908, 178,203 long tons were imported, valued at \$1,350,223, as against 209,021 tons in 1907, valued at \$1,793,143. India furnished the bulk, and a considerable amount came from Brazil.

PATENTS.

Lead fumes or waste metallic solutions and suspensions; Process for the recovery of marketable products from —. A. Levy-Mond, London. Eng. Pat. 12,317, June 6, 1908.

THE process consists in the utilisation of the small quantity of sulphuretted hydrogen contained in Mond gas and similar gases, for the precipitation of metals from such dilute solutions or suspensions as would otherwise be thrown away, thereby recovering the metals and purifying

the gases at the same time. The dilute metallic solutions or suspensions may be used instead of water for the rubbers, &c., of the gas plant, the precipitated metallic sulphides being then obtained in intimate admixture with the solid fuel particles of the crude gas, thus affording an easier reduction to metal in furnaces. The formation of sulphate fume in gas-fired lead furnaces may be obviated by the use of the purified gas.—W. E. F. P.

last furnace dust; Manufacture of briquettes from —. W. Schumacher, Osnabrück, Germany. Eng. Pat. 14,399, July 7, 1908.

THE patent relates to the addition of certain soluble salts to blast-furnace dust, or to mixtures of this with fine ores, powdered slags, &c., whereby the latent hydraulic binding capacity of the dust or mixture is set in action or increased. The chlorides and sulphates of the alkaline-earths, or the metals of the iron group, are the most effective, and are added in the form of aqueous solution, $\frac{1}{4}$ to 1 per cent. of the salt, or mixture of salts, being sufficient in most cases. The mixture is pressed into blocks which harden in a few hours, the hardening effect being intensified by the action of steam under pressure. Binding materials containing lime, or bodies from which calcium hydroxide is liberated, act disadvantageously upon the hardening process.—W. E. F. P.

powdered, residual or friable substances [pyrites, &c.]; Agglomeration or hardening of —. H. Delporte. Fr. Pat. 398,615, Jan. 19, 1909. Under Int. Conv., Jan. 18, 1909.

THE material, which may consist of roasted pyrites, blast-furnace dust or other residual products, is mixed with a certain proportion of coal-schist and the whole crushed very finely, water or other liquid (such as tar) being added, if necessary, so as to obtain a more or less consistent paste. During this operation, the aluminium silicates become uniformly distributed throughout the mass, forming a species of skeleton which binds together the pulverulent portions and so consolidates the whole. The process is assisted by the interposed particles of carbon and by the liquid added. The product may then be moulded into briquettes with or without pressure, according to the hardness it is desired to obtain, or it may be incorporated with other substances. The process of agglutination by the silicates may be advanced still further, and a more compact mass obtained, by a final drying or burning in air. The method may be applied in order to hasten the setting of ordinary and hydraulic cements or mortars.—C. A. W.

blast furnaces; Method and means for utilising the waste heat of —. A. Pfoser, Achern i/Baden, Germany. Eng. Pat. 14,511, July 8, 1908.

THE invention has for its object the better utilisation of the waste heat of masonry regenerators in blast-furnaces by the attachment of tubular metal air-heaters, such as described in Eng. Pats. 16,690 of 1907, 16,411 of 1884 and 3717 of 1876 (this J., 1908, 750). The heated air, instead of proceeding to the blast-furnace through the generator arranged for "air," passes directly to that arranged for "gas," the combustion of the gas resulting in an increase in temperature of the regenerator and of the blast air.—W. E. F. P.

slag; Manufacture of open-hearth —. T. S. Blair, jun., Elmhurst, Ill., Assignor to Blair Engineering Co., Chicago, Ill. U.S. Pat. 927,097, July 6, 1909.

IRON is first subjected to an acid Bessemer process. The metal and slag from this treatment are poured into a ladle to which lime is also added to convert the slag into basic slag. The whole is then charged into an open-hearth furnace, and the metal from other acid Bessemer treatments is added, the different converter charges being blown to different carbon contents.—A. G. L.

cementation process. E. Ferminne. Fr. Pat. 398,570, Jan. 16, 1909.

ABOUT 20–25 per cent. by weight of common salt (sodium chloride) is added to the usual cementation powder,

consisting of wood charcoal, and charred hide and horn. It is claimed that the cementation produced is more regular than when no salt is used.—A. G. L.

Tool and high-speed steel; Art of producing from foundry iron a product having cutting and other properties of high-grade — and metal product from cast iron. E. A. Custer, Philadelphia, Pa., Assignor to The Custer Sandless Casting Co., Delaware. U.S. Pats. 927,495 and 927,496, July 13, 1909.

THE process consists in quickly chilling molten foundry iron (with or without the previous addition of tungsten, nickel, vanadium, &c.) in a permanent metal mould, to the setting point, and then quickly cooling in a fluid bath to fix the homogeneity of the structure so established. The product, whilst retaining the appearance and chemical composition of cast iron, is capable of taking a temper and becoming permanently magnetised.—W. E. F. P.

Manganese ore for the production of briquettes; Treatment of —. A. Gutensohn, London. Eng. Pat. 17,246, Aug. 17, 1908.

CONCENTRATED manganese ore is mixed with 0.25 part of boric acid (or 0.5 part of borax) and 0.3 part of yellow ochre, and heated to redness, allowed to cool, and ground to powder. This powder is added to the ground manganese ore in the proportion of 3 per cent. The whole is heated to a semi-molten state, raked, and pressed into moulds to produce solid briquettes.—J. W. H.

Ores; Method of treating —. W. Kemp, Tucson, Ariz. U.S. Pat. 846,216, March 5, 1907.

THE method consists in treating the ore in the furnace described in Fr. Pat. 358,645 of 1905 (this J., 1906, 270). —O. F. H.

[Refractory] ores; Method of treating —, process of condensing fumes, and condenser. H. A. Hogel, New York. U.S. Pats. 927,046, 927,241, and 926,943, July 6, 1909.

THE ore is mixed with salt and if necessary with sulphur, and then heated and stirred in an oxidising atmosphere until the required metals (lead, copper, silver, gold, &c.) are volatilised. The fumes are conducted into a special condenser, where they are intimately mixed with air and a constantly circulating supply of water. During each circulation, the water is cooled and the admixed air allowed to escape. When the liquor is saturated with the soluble compounds from the fumes, it is run off and the solid residue and solution treated separately for the contained metals. The condenser used consists of a tubular boiler for the partial cooling of the fumes, and a closed circulating system of tanks and connecting pipes, in which the volatilised products are circulated by means of water-jet aspirators and pumps, one of the tanks being provided with a water seal, to permit the escape of the admixed air and gases.—F. R.

Ores and analogous substances; Treatment of —. A. A. Lockwood and M. R. A. Samuel. Fr. Pat. 398,660, Jan. 20, 1909.

THE method is intended primarily for the magnetic separation of ores, tailings, and concentrates. The material to be treated, is mixed, preferably in the form of an acidified paste, with particles of a magnetic or magnetisable substance and with a liquid which adheres to certain of the mineral components in preference to others, so that these alone remain attached to the magnetic constituents. The whole mixture is then exposed to a magnetic field in the usual way. In certain cases, of course, it may not be necessary to make any further addition of magnetic substances to an ore, which may contain a sufficiency in its natural condition. In an example given, with reference to a sample of Broken Hill zinc tailings containing 18.78 per cent. of zinc and 5.14 per cent. of lead, the ore was agitated with dilute sulphuric acid and the pulp so obtained, mixed with two parts by weight of finely-crushed cast iron and one part of coal tar. After further agitation and the addition of water, the mass was passed into the separator.—C. A. W.

Furnace; Roasting —. H. A. Hogel, New York. U.S. Pat. 926,942, July 6, 1909.

THE furnace consists of a brick-lined cylinder, rotating about its long axis at a small angle from the horizontal. The alternate longitudinal rows of fireclay bricks are made with a triangular cross-section and project somewhat towards the centre of the cylinder, forming shelves for the ore. The ends of the cylinder are surrounded by, but not in contact with, stationary caps which are arranged to deliver an annular blast of air into their open ends. Gas and ore inlets and outlets are provided in the upper and lower caps respectively. The furnace is adapted to run in series, the ore from the highest cylinder discharging into the upper end of the next, &c. —F. R.

Metallurgical furnace. R. G. Reilly, Corona, N.Y., Assignor to North American Reduction Co., Arizona. U.S. Pat. 927,283, July 6, 1909.

THE furnace consists of a feed chamber and of a combustion chamber surrounded by a jacket in which air is heated. This hot air is led to a number of hollow grate-bars provided with perforated nozzles and placed at the bottom of the combustion chamber. A hopper is provided below the grate, the ore finally passing into a passage below the hopper.—A. G. L.

Furnace; Movable and dismantlable — for the treatment of minerals and extraction of metals contained therein. E. Reetzka. Fr. Pat. 397,760, Dec. 19, 1908.

THE furnace is designed for the treatment of minerals at the mines. It consists essentially of a double-walled cylindrical chamber surmounted by a chimney and connected below to a conical portion, also double-walled, which ends in a grate of fire-bars. The whole is supported on four pillars. The conical portion of the furnace communicates with the chimney by four valved conduits; it is also provided with ports. The cylindrical part is provided in its upper portion with four openings for the introduction of ore, fuel, etc. Water is circulated between the double walls of the cylindrical and conical portions of the furnace, and also through eight vertical and horizontal tubes which are placed within the cylindrical portion, and help to cool the same.—A. G. L.

[*Nickel-manganese*] *alloys; Process of making* —. J. T. H. Dempster, Schenectady, N.Y., Assignor to General Electric Co., New York. U.S. Pat. 926,980, July 6, 1909.

NICKEL is first melted with a decarbonising agent in a clay-lined crucible to reduce the quantity of carbon present. Other metals (e.g., chromium, or chromium and iron) and manganese are then successively added, and the mixture is cast before the manganese attacks the clay lining.—A. G. L.

Alloys of zinc with copper; Process of making —. S. Elliott, Newton, Mass. U.S. Pat. 927,843, July 13, 1909.

THE process consists in adding the copper to the molten zinc, and raising the temperature to the melting point of the required alloy.—W. E. F. P.

Zinc retorts; Condensation of the exhaust gases from —. Stewarts and Lloyds, Ltd. Fr. Pat. 397,731, Dec. 21, 1908.

THE gases as they emerge from the mouths of the retorts are made to pass through a cylindrical condenser having a length of not less than three metres. This condenser, which is fitted to the retort by means of an air-tight joint of asbestos, is almost entirely closed at its opposite extremity by a plug, an aperture being however arranged in the latter for the escape of the residual gases. Along its whole length, at certain intervals, the passage is obstructed by partitions or baffle-plates provided with small holes and movable, when necessary, on horizontal axes. In this way any zinc dust, which may tend to accumulate within the

perforations, may be readily removed. In order to avoid explosions within the tube, apertures are provided along the top; these are kept closed under normal conditions by means of flap covers.—C. A. W.

Metals; Soldering of —. Cie. Française d'Acétylène dissous. Fr. Pat. 398,090, March 14, 1908.

THE auxiliary substances, such as fluxes, cleaning agents, etc., are previously incorporated with the mass, or deposited on the surface of the soldering metal. The latter, for this purpose, may be in the form of a bundle of sticks, or in any other suitable condition. In this way the flux may be brought, in any proportions desired, exactly to the position where the weld is required, so that all waste is avoided. —C. A. W.

Aluminium; Soldering of —. F. Stalder, E. Scholl, and G. Dubach. Fr. Pat. 398,245, Jan. 2, 1909.

THE pieces of aluminium to be connected are cleaned covered with pure sulphur and passed through a flame. The sulphur having melted, the weld is made at the required point by means of an alloy composed of equal parts of tin and zinc. After application of the solder, a piece of pure tin is passed over the heated weld.—C. A. W.

Molybdenite; Process of treating commercially mineral containing —. A. Leduc. Fr. Pat. 398,539, March 25, 1908.

CRUSHED molybdenite is heated at a temperature slightly below a red heat in a mixed current of air and gaseous hydrogen chloride, molybdenum oxychloride ($\text{MoO}_3, 2\text{HCl}$) being volatilised. This is condensed and dissolved in water, and the aqueous solution evaporated to obtain molybdic acid.—A. G. L.

Metallic paint. Fr. Pat. 398,084. See XIII A.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A).—ELECTRO-CHEMISTRY.

Cathode-dish; Graphite —. J. W. Turrentine, Amer. Electrochem. Soc., Niagara Falls, May, 1909. Electrochem. and Met. Ind., 1909, 6, 279.

SIMPLE graphite electrodes, paraffined in order to overcome the porosity, are described, and details are given of the preparation of a graphite cathode dish. Where great accuracy is not required, these contrivances may be used in the place of platinum as insoluble electrode in electro-chemical experiments.—C. A. W.

Electrical conductivity of solutions; Influence of pressure on —. F. Körber. Z. physik. Chem., 1909, 67, 212–248.

PRESSURE increases the electrical conductivity of solutions but its influence diminishes as the temperature rises. The isotherms of change of resistance, in the case of dilute solutions of potassium chloride, show a minimum at each temperature, though the curves flatten as the temperature rises. The temperature-coefficient of the influence of pressure on the conductivity has (for potassium chloride) a maximum at 30°, and from 50° to 100° C. remains constant. In the case of sodium chloride, the influence of pressure on the ionic friction of the dissolved electrolyte and on the viscosity of the solvent, are alike, but this does not hold in the case of electrolytes—the influence of pressure on ionic friction being different for different ions. In dilute solutions of strong binary electrolytes the influence of pressure on ionic friction is additive and can be deduced by summation of the effects on the separate ions. Usually, the effect of pressure in lessening ionic friction is less for ions of high than of low atomic weight, but potassium and sodium form an exception to this. The isotherms of effect of pressure on ionic friction approach one another more nearly at higher temperatures.

but the hydrogen ion forms an exception to this. The influence of pressure on the conductivity of strong electrolytes is, even up to pressures of 3000 atmospheres, independent of the concentration till high concentrations are reached, when it begins to lessen. At very low concentrations it increases, because of the effect on the conductivity of the solvent. The isobars of pressure-change of conductivity in relation to concentration show a conspicuous maximum, at the same pressure for all concentrations. The figures for the effect of pressure on the dissociation of acetic acid at 20° C., calculated from the conductivity isotherms of sodium chloride and acetate, hydrochloric and acetic acids, agree well with those calculated from Planck's formula of the dependence of dissociation-constants on pressure, but at higher temperatures they show higher values for the effect of pressure.

Lash steel process and the electric furnace. F. A. J. Fitzgerald. Amer. Electrochem. Soc., Niagara Falls, May, 1909. Electrochem. and Met. Ind., 1909, 6, 268.

THE author considers the Lash steel process as worked in the ordinary open-hearth furnace and explains how it may be applied to the electric furnace. The process, which consists essentially in the smelting of an intimate mixture of iron ore, carbon, fluxes, and cast iron borings or granulated pig-iron, may, it is stated, be more advantageously carried out in the electric furnace, where the atmosphere is neutral. The oxidising atmosphere of the open-hearth furnace renders the control of the carbon content in the resulting steel a matter of difficulty, and, moreover, a certain amount of pig-iron or scrap has always to be added in addition to the Lash mixture. In the electric furnace this should not be required. As to the question whether the addition of metallic iron is necessary at all, experiments have been made comparing the reaction of the Lash mixture and a charge containing no granulated pig-iron. In the latter case it was shown that not only was the power consumption excessive, but the mixture showed a tendency to boil or froth instead of melting down quietly. Moreover, when no pig-iron was used, the consumption of electrodes in an arc furnace was very much greater. The presence of the pig-iron, in fact, reduces the amount of energy required to produce a unit weight of metal from the ore.—C. A. W.

Copper electro-deposition baths; Determination of the free acid in —. M. de Dehaisieux. Bull. Soc. Chim. Belg., 1909, 23, 310—314.

THE presence of excess of free acid in a copper electro-deposition bath has an important influence on the properties of the metal deposited, and it is necessary to have a rapid method of controlling the free acidity. Sims (Chem.

News, 1907, 253) proposed to add 4 drops of methyl orange to the solution diluted so that 100 c.c. contained 3 grms. of copper sulphate, and then to titrate with sodium bicarbonate till a green tint was obtained. The author confirms this method and shows that $N/2$ sulphuric acid and sodium bicarbonate can be titrated with accuracy in presence of varying amounts of copper sulphate. Conductivity curves for the neutralisation of free acid with increasing amounts of sodium hydroxide in presence of copper sulphate, show a fall till the neutrality point towards methyl orange is reached; the curve then remains flat till the copper salt has been precipitated, and rises again to the neutral point towards phenolphthalein.—E. F. A.

Electro-deposited alloys; The conditions which determine the composition of —. Part I. Copper-zinc alloys. S. Field. Faraday Soc., June 29, 1909. [Advance proof.]

THE effect of temperature, current density and composition of solution upon the electro-deposition of brass from cyanide solutions was investigated. Such solutions presented advantages in that copper and zinc ions were present in small quantities and were readily discharged together, although slight variations of E.M.F. gave rise to change of colour and composition of deposit. The products of anodic oxidation in such solutions were, however, ordinarily insoluble, and care had to be taken that insulating layers of insoluble cyanides did not form on the anodes. Experiments with solutions of copper formed by dissolving precipitated copper carbonate in a solution of potassium cyanide, showed that the warmed and agitated (40 to 50 per cent.) solution gave the best results, an anode efficiency of over 100 per cent., and a cathode efficiency of 95 to 98 per cent. being obtained. The anode remained clear and bright. The abnormal anode efficiency was partly due to the increased solvent action of the solution when agitated and also to the slight disintegration of the plate. The brassing solution was prepared by dissolving 100 grms. of copper-potassium cyanide and 100 grms. of zinc-potassium cyanide in water and making up the solution to 1200 c.c.; a mixture of zinc and copper carbonates was then agitated with it to remove the excess of cyanide, and the solution filtered. The solution was maintained at a temperature of 50° to 60° C. by means of a glass steam-coil. The composition of the brass deposit could be roughly deduced from the ratio of the weight of brass deposited to the weight of copper deposited in the voltameter. If the deposit were entirely copper, this ratio would be 2 and if entirely zinc, 1.028. The deposits obtained with the above solution although almost quantitative, were not physically uniform or good. The percentage of zinc in the deposit increased with an increase in current density, though in this solution it was below that of ordinary brass. The potential difference was low, the statements of the text-books being incorrect on this point. The zinc anodes became covered with copper by simple immersion, and it was only with heavy current densities that this deposit disappeared. By the addition of zinc cyanide to the solution, the percentage of zinc in the deposit increased, especially with high current densities, but the anode became less soluble. Copper was more freely deposited, although zinc preponderated in the solution. Upon dilution of the solution, the percentage of zinc in the deposit increased on account of the higher potential difference required to maintain the same current density. Quantitative deposition only occurred in warm solutions and an increase of temperature increased the percentage of copper in the deposit. On addition of free cyanide there was more difficulty in maintaining uniform deposition at ordinary temperatures while the rate of agitation had great effect on the deposit, which was always rough. The amount of gas generated was also reduced. With appreciable amounts of free cyanide the percentage of copper was always high even with high current density. Free cyanide, other than by dissolving the anode products, added little conductance to the depositing cell. These cyanide solutions were subject to continual changes of composition which soon prevented the exact repetition of similar effects.—J. W. H.

Alkali hydroxides; Electrolysis of fused — and solubility of the alkali metals in the melt. G. v. Hevesy. Z. Elektrochem., 1909, 15, 529—536.

ANHYDROUS mixtures of sodium and sodium hydroxide were fused together in closed metal cylinders at different temperatures for varying lengths of time. The cylinders were then cooled rapidly, opened, the metal separated from the hydroxide melt, and the free metal present in the latter determined, as well as the total alkalinity of the hydroxide melt. For temperatures up to 500° C., brass cylinders were used; for higher temperatures, nickel was employed; in both cases the cylinder containing the melt was enclosed in an outer cylinder of iron, also tightly closed. It was found that sodium is appreciably soluble in sodium hydroxide, 100 grms. of the latter dissolving 25.3 grms. of sodium at 480° C., 10.1 at 600°, and 6.9 at 800°. The solubility was independent of the duration of heating, and also of the proportion of sodium present, provided only that the latter was present in excess. Addition of metals such as thallium, cadmium, and gold, which produce a lowering of the freezing-point of sodium, depress the solubility of the latter by the amount required by the theory of solutions, as long as the metallic additions are not too large. Addition of zinc, on the other hand, which does not lower the freezing-point of sodium, has also no effect on the solubility of sodium in sodium hydroxide. Sodium diffuses very rapidly into sodium hydroxide, the velocity increasing with increase of temperature. Thus, on electrolyzing sodium hydroxide at 315°—340°, the current efficiency was 27 per cent.; at 360°—390° C. the current efficiency was nil. Addition of sodium chloride, bromide, and iodide had no effect on the solubility of sodium in sodium hydroxide. Similar results were obtained for mixtures of potassium and potassium hydroxide, but the solubility of the metal in the hydroxide is much smaller than for sodium, being 7.8—8.9 grms. of metal for 100 grms. of hydroxide at 480°, and 0.5—1.3 at 700° C. The velocity of diffusion is also much smaller; the electrolysis of potassium hydroxide at 320°—340° gave a current efficiency of 55 per cent., and at 365°—410° C. of 26 per cent.—A. G. L.

PATENTS.

Arsenical ores and speiss; Process of treating —. A. G. Betts, Troy, N.Y. U.S. Pat. 927,024, July 6, 1909.

SPEISS is treated by dissolving it as anode in a solution of a lead salt, lead being at the same time deposited on the cathode. Arsenic is "cemented" from the solution by means of metallic lead, and the metal contained in the speiss is deposited from the solution by electrolysis, using a lead anode, after which the solution left is used again for the treatment of a fresh quantity of speiss.

—A. G. L.

Ores or other materials; Treatment of — by electrical heating. Soc. di Montepioni. Fr. Pat. 397,999, Dec. 29, 1908.

THE apparatus is intended for the calcination and dehydration of iron ores, and, with certain modifications, for the reduction and recovery of volatile metals such as mercury, zinc or antimony. In its most simple form, it consists essentially of an upright tubular retort embedded in masonry and having walls composed of some refractory substance which conducts electricity, such as graphite or a mixture of graphite with any refractory earth. It may have any shape, circular or oval, but in every case the thickness of the walls at any point must be inversely as the temperature it is desired to attain there. The electrodes are arranged at the two opposite extremities of the apparatus, where the walls are very thick, so that, the current being made to run around the retort, the greatest heat will be developed at those central portions where the walls are thinnest. The velocity of the reaction is governed by the movement of a worm-conveyor which moves in a channel beneath the furnace and carries away the ore as it falls through the bottom. If it be necessary to recover the volatile products, as in the case of mercury or antimony ores, the arrangement is modified, the top of the retort being covered by a plate of refractory

material containing a central hole through which the ore is fed by means of a hopper. In this way an annular space is left free at the top, where the volatile gases collect and pass away through flues provided for the purpose. A further modification is necessary when the furnace is used for the distillation and recovery of zinc metal from its ores. In this case the retort is pierced at two points where the walls are thinnest, so that it communicates at these points with condensers of the usual type, embedded in the masonry.—C. A. W.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

African vegetable fats; Characteristics of —. M. Krause and Diesselhorst. Tropicplanzer Jahrg., 1909, 13 [6]. Chem. Rev. Fett- u. Harz-Ind., 1909, 16, 200—201.

Allanblackia Stehlmanni fat.—The tree, which is found in East Africa, produces a fruit containing about 30 seeds of the size and form of chestnuts, from which 54.5 per cent. of fat can be extracted. The fat, which is used locally for food, resembles lanoline in its action upon the skin. It could be used in the soap and stearin manufactures, for cosmetics, and possibly as a cheap substitute for lanoline. As the tree produces its fruit in great abundance, it would probably repay cultivation. The fat had the following characteristics:—Sp. gr. at 17.5° C., 0.8736; m. pt., 43° to 46° C.; refractive index at 50° C., n_D^{50} = 1.4503; saponification value, 188.6; iodine value, 37.48; m. pt. of fatty acids, 60° C.; and iodine value of fatty acids, 38.25.

Oil of Plukenetia conophora.—The plant, which is extensively cultivated in the fields in the district of Ossidinge (Cameroons), produces seeds, of about the size of a walnut. The kernels yielded 53.8 per cent. of a drying oil closely resembling linseed oil in its properties. It is used by the natives as an edible oil, and would be valuable as a substitute for linseed oil in the manufacture of varnish and linoleum. The oil had the following values:—Sp. gr., at 17.5° C., 0.9354; solidification point, —33° C.; saponification value, 192; iodine value, 177.3; refractive index at 17.5° C., $n_D^{17.5}$ = 1.4830; and iodine value of fatty acids, 187.4. The residue of kernel, after removal of the oil, contained 7.3 per cent. of nitrogen.

Oil of Ojok fruit.—The nuts of this tree, common in the district of Ossidinge, contained 52.24 per cent. of an oil with a pleasant taste. The expressed oil, which could be used as a foodstuff, had the following characteristics:—Sp. gr., 0.9333; solidification point, —22° C.; refractive index at 17.5° C., $n_D^{17.5}$ = 1.5068; saponification value, 189.9; and iodine value, 123.9.—C. A. M.

Halogen absorption of oils by the methods of Hübl, Wijs, Hanus, and McIlhenny; Comparative examination of the —. J. S. Remington and H. Lancaster. Brit. Pharm. Conf., Newcastle, July, 1909.

THE authors arrive at the following conclusions respecting the different methods for determining the halogen absorption of oils. Much better results are obtained by the Wijs than by the Hübl and Hanus methods. To get quick and accurate results by the Wijs method, there must be an excess of 70—80 per cent. of halogen. To get the maximum absorption by this method, two hours must be allowed for drying oils such as linseed oil, an hour for semi-drying oils, and half-an-hour for non-drying oils. The mixed Hübl solution deteriorates rapidly after 24 hours, whereas the Wijs and Hanus solutions will keep for several months. The McIlhenny bromine method is much superior to any of the above three methods in that the absorption is practically instantaneous, the solutions are easily prepared and keep well, and the method distinguishes between the bromine absorbed and the bromine substituted.—F. SUDS.

Miscibility curves of liquids; Use of — in analysis. Application of the method to edible oils. E. Louise. Comptes rend., 1909, 149, 284—286.

IN a previous communication (this J., 1907, 932) it was shown that oils formed double mixtures with acetone, and

that each oil had a characteristic *temperature of miscibility*. Further experiments have shown that in order to obtain constant values with the same kind of oil, it is essential that the sample should be dry, and that the acetone should always be of a definite standard. For this purpose the freed from glycerides solidifying above 15°C . is dried 3 days *in vacuo* over sulphuric acid. The acetone is taken with calcined sodium carbonate and filtered, the acetone mixed with dry sodium carbonate and distilled, and the portion distilling at 56° – 57°C . collected. To obtain a product with a constant amount of moisture, this acetone is standardised on petroleum spirit, which has itself been standardised on absolute alcohol. The latter forms a double mixture with petroleum spirit distilling at 210° – 215°C ., and the petroleum spirit forms a double mixture with acetone. Hence, by determining the respective *temperatures of miscibility*, a typical acetone can be prepared. This is kept in a vessel which will deliver portions of 20 c.c., and into which only dry air is admitted. It is shown that the curves of miscibility obtained with an acetone thus standardised are almost parallel, and very close to each other in the case of different samples of the same kind of oil. The curves given by cotton-seed and sesame oils fall below and are far removed from the curves of olive oil, whilst the curves of arachis fall above those of olive oils, without, however, being very far from them. It is possible by plotting the curves to determine approximately the proportion of sesame and cotton-seed oils in an adulterated sample of olive oil, and in the case of arachis oil the results will be less exact. The determination of *temperatures of miscibility* may also be used in the determination of water in *e.g.* oils, and in the analysis of petroleum spirit, glycerin, essential oils, &c.—C. A. M.

Parsley-seed oil; Unsaponifiable constituents of —. I. Matthes and W. Heintz. Ber. deuts. pharm. Ges., 1909, 19, 325–328.

A specimen of oil examined was of a dark green colour, and had a bitter pungent taste. It dissolved readily in ether, chloroform and carbon bisulphide and in a mixture of alcohol and ether. Its analytical values were as follows: sp. gr. at 15°C ., 0.9720; refractive index at 40°C ., 1.424; saponification value, 190.9; and iodine value, 187. A solution of the oil in a mixture of equal parts of alcohol and ether, yielded, on standing, a crystalline deposit with the characteristics described by Vongerichten and Köhler (this J., 1909, 662). This fat contained an unsaponifiable portion composed of a yellow oil with an aromatic odour, and of crystals suspended in it. The crystalline part, after treatment with warm alcohol and repeated recrystallisation from ether, melted at 69°C ., and had a composition corresponding to the formula $\text{C}_{28}\text{H}_{48}$, and a mean molecular weight of 289.1 ($\text{C}_{28}\text{H}_{48}$ = 284). To this hydrocarbon, which did not absorb iodine and gave the phytosterol reaction, the name "*petrosilane*" was given. It is mentioned that Etard isolated a hydrocarbon with the same formula and m. pt. from *Bryonia cretica*, and that Matthes and Sander (this J., 1908, 987) found a similar hydrocarbon in laurel-seed oil, which differed, however, from petrosilane and bryonane in being soluble in boiling absolute alcohol. Two hydrocarbons of the same composition and of similar form and solubility (m. pts. 60.5° and 67°C .) were also found by Schwalb in wax. The solid portion of the unsaponifiable matter soluble in alcohol yielded a substance melting at 88°C ., and corresponding in properties with melissyl alcohol crystals, melting at 133° to 145°C . and giving the phytosterol reaction. These consisted of a mixture of several compounds. The liquid soluble portion, separated from the alcoholic solution by chilling the liquid, was a yellowish brown oil with an iodine value of 111.75 and refractive index at 40°C . of 1.5154. The total quantity of the unsaponifiable matter in the parsley seed oil was about 14 per cent.—C. A. M.

Canic compounds [Oils]; Catalytic oxidation and reduction of —. S. Fokin. Z. angew. Chem., 1909, 22, 1451–1459; 1492–1502.

The author gives details of the experiments on which were based his conclusions on the drying of fatty oils (this J.,

1907, 1149; 1909, 98). He now groups certain metals found to accelerate the oxidation in an order different from that previously given:—(1) Cobalt, manganese, chromium, nickel, platinum, palladium. (2) Barium, lead, cerium. Where these metals effect a reduction their arrangement is in the reverse order. The phenomenon of a simple absorption of oxygen by unsaturated compounds, without the formation of decomposition products, may be brought about through the agency of metallic oxides. In such cases only about one-half of the theoretical amount of oxygen is absorbed, *i.e.* the autoxidation is semi-molecular. Thus, in an experiment with tung oil the absorption of oxygen in a film test, with a cobalt salt as the sicative, reached 8.6 per cent. in 24 hours, or "approximately half the theoretical amount (10 per cent.)." In a second experiment the plate was heated to 40 – 45°C . for 5 minutes, after having been exposed for 3 hours, and the increase in weight after 26½ hours was then 18.7 per cent.; so that here there was molecular autoxidation. After standing for a short time the varnish became slowly polymerised. With the aid of a cobalt sicative a rapidly drying varnish may be prepared from sunflower oil, which has hitherto been regarded as unsuitable for the purpose. Thus, a film of the oil exposed to the air at 17.5°C . had increased in weight by 8.8 per cent. in 19 hours. A film of the same oil containing 4 per cent. of cobalt sicative (cobalt, 0.33 per cent.) was no longer "tacky" after 6 hours, and after 17 hours' exposure had gained 12.1 per cent. in weight. Almond oil containing the cobalt salt showed an increase of 4.1 per cent. in weight after 12 hours' exposure, and of 4.7 per cent. after 30 hours' exposure under a pressure of 15 atmospheres (half the theoretical absorption = 5.3 per cent.). In each case the oil had become thicker, but no "skin" had formed. Linseed oil fatty acids mixed with one-tenth of the amount of cobaltous oxide required to form a neutral salt, heated at 130° to 150°C ., to dissolve the cobalt salt, and then exposed in a film at the ordinary temperature, showed a maximum increase in weight of 9.1 per cent. after about 18 hours. The film was not "tacky," and differed from linoleum in being soluble in alcohol. In like manner, a fish-liver oil containing 0.45 per cent. of cobalt, absorbed 9.64 per cent. of oxygen after 535 minutes at 18.5°C . (calculated amount = 9.89 per cent.). With regard to the action of the air upon the drying process, there is a great difference between the results obtained with free access and with limited access of air. Thus linseed oil left in a loosely-closed flask for 10 years had changed into a very heavy viscous fluid, which was quite insoluble in fresh linseed oil. It had a molecular weight (Raoult) of 1137, whereas a fully oxidised linseed oil would only have a molecular weight of 1062 (corresponding to an iodine value of 180). A film of this product exposed for 200 hours increased in weight by 7.24 per cent. "*Blown*" cobalt varnish:—Air was drawn through a cobalt varnish (Co = 0.33 per cent.), which before treatment yielded a film that ceased to be "tacky" after an exposure of 2 to 2½ hours. After the air had passed through it for 7 hours at the ordinary temperature the liquid thickened, and then yielded a film which remained "tacky" after an exposure of 1 hour 55 minutes. But after continuing the treatment for an additional 4½ hours the films were no longer "tacky" after 1¼ to 1½ hours. When air was drawn through the varnish for 7½ hours at 50°C ., the liquid became viscous and yielded a "non-tacky" film in 40 to 45 minutes. The rose colour had changed to dark brown, and the product had become nearly insoluble in petroleum spirit. A mixture of the insoluble portion with turpentine oil yielded a film devoid of "tackiness" in 30 minutes. Nickel varnish "blown" for 9 hours at 55° to 60°C . yielded a "non-tacky" film in 13½ hours. Further details are also given of experiments on the catalytic reduction of organic compounds with the aid of metals (see this J., 1906, 35; 1907, 169, 1149; 1908, 878; 1909, 98). The metals can be grouped into those which, like palladium and cobalt, form definite hydrides; and those which, like platinum and nickel, have not been proved to form such definite hydrides. The latter class gives the best results in reduction catalyses. It is shown that in the presence of 2 per cent. of platinum the speed of the reaction is so rapid that hydrogen absorption may be used as an

analytical method of determining the amount of a given unsaturated compound in a mixture (see this J., 1908, 878). By the use of these metallic catalytic agents it is possible to effect the reduction of nitro-, halogen and other derivatives of organic compounds, and probably also of aldehydes and ketenes. In the case of cyclic compounds with double linkages there is no appreciable reaction at temperatures below 100° C.—C. A. M.

Beeswax; Analysis of — H. Ryan. Proc. Roy. Dublin Soc., 1909, 12, 210—215.

SIMULTANEOUSLY with, but independently of Hehner (Soc. Public Analysts, Jan., 1909), the author has employed a method of determining beeswax in complex wax mixtures, which is based on the assumption that the molecular weight of cerotic acid is higher than that of any other "free" acid that may occur in such mixtures intended for the manufacture of candles. The acid value is first determined by heating 4 grms. of the wax with 60 c.c. of neutral absolute alcohol, and titrating the liquid, as soon as it boils, with $N/2$ alcoholic potassium hydroxide solution. The warm mixture is next mixed with 40 grms. of clean dry sand, and evaporated to dryness in a steam oven, and the residue extracted with petroleum spirit of low boiling point for about 4 hours. The extract is evaporated in a weighed flask, and the residue of "ester" dried in the oven until constant in weight. The difference between 100 and the percentage of ester gives the amount of free acids in the wax, and from these results the acid value of the free acids can be calculated. Assuming that the only free acids present, are crude cerotic and commercial stearic and palmitic acids, the percentage of the cerotic acid may be calculated on the assumption that its mean acid value in unbleached beeswax is 146, whilst the corresponding value for commercial stearic acid is 206. The percentage by weight of the crude cerotic acid, multiplied by the factor 7.5, gives the percentage of unbleached wax in the sample. Analyses of samples of genuine beeswax from Ireland, Chili, Sierra Leone, and Madagascar are given to show that beeswax of widely different origin varies but little in composition. Since montanic acid from montana wax (see p. 878) has a higher molecular weight than that of cerotic acid, a composition wax having acid, ester, ratio and iodine values and molecular weight of free acids identical with those of beeswax could be prepared by mixing montana wax with spermaceti, carnauba wax, and ceresin. Such a mixture was obtained by melting together 2 grms. of montana wax, 0.3 gm. of pure stearic acid, 5 grms. of spermaceti, 1.5 gm. of carnauba wax, and 1.2 gm. of ceresin. This preparation gave values very similar to those of genuine beeswax, with the exception that the m. pt. varied from 46° to 67° C. Apart from this, the mixture would pass as pure beeswax if examined by Hehner's method or that described above. It contains 21.4 per cent. of hydrocarbons, however, whereas beeswax only contains 11 to 14 per cent. Again, by hydrolysing the "ester" obtained in the determination of the free acids and separating the insoluble acids from the resulting soap, it will be found that their mean molecular weight is greater than that of the combined acids in myricin. Assuming these acids to consist of only palmitic and cerotic acids, the proportion of the latter, and the corresponding amount of carnauba wax or Chinese wax may be calculated. The percentage of cerotic acid found by the author in bleached beeswax was 13.32 per cent., whilst Hehner found 15.8 per cent. —C. A. M.

Cotton seed at New Orleans. For. Ann. Series, 1909.

The exports of cotton-seed oil, stearine, cake, meal, and other products of the cotton-seed industry are increasing year by year. The value of the cotton seed sent to the crushing mills may be reckoned as worth about £21,000,000 when manufactured. There are 450 mills for crushing cotton seed in the United States, with a capital of £20,000,000, giving employment to 60,000 persons.

PATENTS.

Oil; Process of separating water from — J. W. Pittock, Assignor to The Oil and Waste Saving Machine Co., Philadelphia, Pa. U.S. Pat. 928,280, July 20, 1909.

The finely-divided mixture of oil and water, which may first be filtered, is projected, with or without the aid of centrifugal force, against a surface heated to a temperature sufficient to evaporate the water without decomposing the oil. A current of air may be used to accelerate the process.—C. A. M.

Oils that have been used for lubrication; Process and apparatus for purifying — O. F. Egeberg. Fr. Pat. 398,411, Jan. 11, 1909.

THE oil is heated at a low temperature (preferably between 30 and 50° C.) in a partial vacuum in order to expel water and is freed from insoluble impurities by filtration. The apparatus claimed for this process consists of a closed jacketed vessel, heated by means of hot water. The top of this vessel ends in a tubular prolongation, which is surrounded by a steam coil (the lower end of which opens into the water jacket) and is enclosed to prevent loss of heat. Within the tubulure is suspended a perforated cone to retain oil mechanically carried forward and return it to the vessel. The steam, still carrying some oil, passes through a coil cooled by water, and the condensed liquid falls into a compartment, an opening in which (controlled by a float) is connected with the vacuum pump. The apparatus is charged from a receptacle in which the spent oil is allowed to stand for the bulk of the water to separate. The water is then siphoned off, whilst the residual oil is drawn up through a tube into the jacketed pan.—C. A. M.

Soap; Manufacture of hygienic — A. Radisson. Fr. Pat. 398,302, Jan. 5, 1909.

ORDINARY soap is dried and incorporated with a certain proportion (say 5 to 15 per cent.) of a substance (such as a metallic or organic peroxides) capable of liberating oxygen on contact with water, and the mixture is formed into pieces of the desired shape.—C. A. M.

Soap press with cooling device. G. A. Khumpp. Ger. Pat. 211,624, Oct. 19, 1907. Addition to Ger. Pat. 126,609 Feb. 3, 1901.

THE patent relates to improvements in the apparatus described in the chief patent, which is fashioned somewhat after the style of a copying press (see Lewkowitsch, this J., 1904, 1100). The cover-plates of adjacent frames are connected by means of a right- and left-handed screw so that they can be simultaneously moved in opposite directions, thus altering the size of the moulds enclosed by the frames.—A. S.

Working up residues from manufacture of cane sugar. Fr. Pat. 397,843. See XVI.

Edible fat. Fr. Pat. 398,241. See XVIII A.

Austria-Hungary. Imports of paints containing lead Ch. of Comm. J., Aug., 1909. [T.R.]

An Austro-Hungarian Decree of April 26th, 1909, provides that all paints and fillers containing lead must have the fact clearly and conspicuously indicated on the receptacle before they can be admitted into the country and put on the market. The decree affects the following products:—Lead ashes, litharge in powder form, yellow and red lead, white lead, sulphate of lead, colours and paints, ground or mixed with varnishes containing lead. The Decree which came into effect on May 1st, 1909, has been issued on sanitary grounds.

PATENTS.

Lithographic and autographic ink. A. Manche, A. Noclain, and A. Chavet. Fr. Pat. 397,923, Dec. 24, 1908.

A LIQUID lithographic and autographic ink which will keep well, and, when dried, be insoluble in water, is prepared by mixing resins, waxes, olein, oleic acid, etc., with water, rendered alkaline and coloured with a dyestuff-derivative of pararosaniline, aniline, or toluidine. Suitable proportions mentioned for the two portions of the mixture are:—(A) Distilled water, 1000 c.c.; Aniline Violet, 1 grms.; Diamond fuchsins, 2 grms.; and ammonia solution, 30 c.c. (B) Beeswax, 60 grms.; rosin, 25 grms.; and olein, 8 grms.—C. A. M.

Metallic paint. H. Gall. Fr. Pat. 398,084, March 13, 1908.

A POWDERED metal, e.g., aluminium, is incorporated with ethyl acetate, preferably containing sufficient nitrocellulose to give to the liquid the consistency of a syrup.—C. A. M.

(B.)—RESINS, VARNISHES.

Rosin oil acids. F. Schulz. Chem. Rev. Fett- u. Harz-Ind., 1909, 16, 186–189.

AN American rosin (type C) yielded on distillation, 3 fractions with the following characteristics:—

Fraction.	Per cent. on rosin.	Colour.	Sp. gr. at 15° C.	Flashing point (open test).	Acid value.
1	3.5	Yellow	0.958	31	53.8
2	10.9	Yellowish brown	0.997	83	63.8
3	10.7	Do.	1.002	85	65.0
4	10.5	Do.	1.006	94	66.6
5	10.8	Violet brown	1.011	98	67.8
6	11.1	Blue	1.010	88	36.4
7	9.7	Bluish-green	1.008	84	30.8
8	12.0	Grass green	1.008	84	30.2
Water, gas, coke	19.8				

In practice, 50 to 60 per cent. of rosin oil (*Harzstocköl*) is obtained before distillation of the "blue oil," and the author, therefore, mixed fractions 2 to 6 (54 per cent. on the rosin), and obtained an oil with the following values:—Sp. gr. at 15° C., 1.005; viscosity at 20° C., 192° (Engler); flashing-point, 92° C., and acid value, 60.5. Three other rosins (type F) yielded 53 to 65 per cent. of rosin oil with sp. gr. of 0.990 to 0.997, and acid value of 34.7 to 47.6, whilst a sample of waste pitch (brewers' pitch) produced 50 per cent. of rosin oil (sp. gr., 0.978; acid value, 19.6) and 27 per cent. of "blue oil" (sp. gr., 0.990; acid value, 7.8). In general, the yield of acids is in accordance with the rules that hold good for "cracking" distillation. With the increase in the height of the oil-vapours the quantity of acids falls. Rapid distillation or the use of a vacuum increases the proportion of acids. The fact that the acid value of the rosin falls during the distillation, has an important bearing on the theory of the distillation process. Thus a rosin with an initial acid value of 160.7 showed values of 155.7 to 157.9 in three experiments after 25 per cent. had been distilled. The rosin acids separated from the united fractions (2 to 6) and dried at 140°–150° C., were closely similar to those yielded by American rosin of type F or G. After purification by being dissolved in benzene and extracted with 4 per cent. sodium hydroxide solution, from which they were again separated by hydrochloric acid, these acids (constituting 18 to 29 per cent. of the rosin oil) melted at 60° C., and had a molecular weight of 291, and an optical rotation at 17° C. of $[\alpha]_D = +45^\circ$ in a 1 per cent. alcoholic solution. They were probably identical with Bischoff and Nastvogel's isosylvinic acid (This., J., 1890, 927).—C. A. M.

Philippine terpenes and essential oils. Manila *chmi* and Balas resin. Bacon. See XX.

PATENT.

Removing varnish, paint, and the like from wood and other surfaces; Composition for —. J. J. Manns, Leytonstone. Eng. Pat. 4592, Feb. 24, 1909.

"OIL lime soap" (2–10 per cent.) and water (1–5 per cent.) are thoroughly incorporated with a mineral oil at a temperature of 180°–190° F., and the whole allowed to cool. To form the composition, solvents such as benzene, naphtha, and methylated spirit are added to the above mixture in suitable proportions. A second form of the composition includes stearine, and another, in addition, wood flour.—J. W. H.

(C.)—INDIA-RUBBER, &c.

Rubber vine; A —. R. F. Bacon. Philip. J. Sci., A., 1909, 4, 166.

THE woody climbing vine, *Parameria philippensis* Radlk., contains a rubber-like gum, which is present to the extent of about 4–5 per cent. in the bark. When extracted by carbon bisulphide it is yellow, but turns black on exposure and becomes tacky. The various species of *Ficus* found in the Philippines are more likely to yield a satisfactory rubber.—F. SHDN.

Antimonium sulphuratum. Alcock. See XX.

Determining antimony in its sulphide preparations Howard and Harrison. See XX.

PATENTS.

Caoutchouc (vulcanised or otherwise) and similar products; Process for the regeneration of —. G. Capelle. Fr. Pat. 398,583, Dec. 15, 1908.

THE caoutchouc to be regenerated is mixed with products of the decomposition of caoutchouc or similar products. Thus the material may be dissolved in the distillate from the dry distillation of caoutchouc or similar substances (gums, resins, etc.), and the caoutchouc separated from the filtered solution. Or the waste rubber may be finely divided and incorporated with the viscid product obtained on superheating caoutchouc or similar products.—C. A. M.

[*Rubber*] *Latex; Products obtained by mixing — with gelatin, glue, starch, casein, gums and other plastic and viscous substances, viscose and other solutions of cellulose, and, in general, with all solutions containing alkali.* See, du Caoutchouc par le Latex. Fr. Pat. 398,705, March 30, 1908.

LATEX prepared and preserved by Morisse's process (Fr. Pats. 360,324 and 360,325 of 1905; this J., 1906, 82 and 487), or other methods, is incorporated with solutions of one or more of the substances mentioned above, to form more or less solid and transparent products, the elasticity of which will depend upon the proportions of materials used, and the mode of vulcanisation subsequently employed.—C. A. M.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Reaction of the tannins; Note on a ——. M. Philip. Collegium, 1909, 249—250.

THE author revives the test suggested by Eitner and Meerkatz (Gerber, 1885), and applies it to the newer tanning materials. 100 c.c. of a 2 per cent. solution of the tannin are digested for a few minutes with 0.5 c.c. of strong sulphuric acid, and after cooling and adding 20 grms. of common salt, the mixture is filtered. In a test-tube, 10 drops of yellow ammonium sulphide are mixed with 15 c.c. of distilled water, $1\frac{1}{2}$ —2 c.c. of the tannin solution are then added, and the whole is shaken and allowed to stand. Characteristic precipitates are obtained, thus:—

Material.	Nature of precipitate.	
	At first.	Later.
Chestnut extract	Brownish	Reddish
Oakwood extract	Yellowish brown	—
Oak bark	Yellowish	Brown
Valonia	Yellow-green	Chamois
Knoppertu	Yellowish	Red-brown
Myrobalans	Greenish yellow	—
Ivix-divi	Light greenish yellow	—
Hemlock	—	Yellow brown
Mallet bark	Yellow brown	—
Mimosa bark	Reddish white	—

No precipitate was obtained with quebracho, mangrove, pine bark, cutch and gambier. The author observes that precipitates are obtained with pyrogallol tannins, but not with those of the catechol group, and hence proposes to detect the former in the latter by means of this reaction, e.g., the presence of myrobalans in quebracho extract.

—H. G. B.

Tanning analysis; International method of ——. Practical trials with nickel basins. Schell. Collegium, 1909, 227.

THE use of pure nickel basins for the evaporation of tannin solutions is not recommended for the following reasons. The nickel appears to be slightly soluble in tannin solutions, the basins being 1—2 mgrms. lighter after each evaporation. The basins being rather thick, cool very slowly; and as they are very porous, it is difficult to obtain a correct weight owing to hygrometric fluctuations during weighing. German chemists find the use of pure silver basins very satisfactory, these possessing none of the disadvantages named above.—H. Br.

Tanning analysis and possible simplifications of the official method; The use of different basins in ——. U. J. Thuau and P. de Korsak. Collegium, 1909, 228—231.

A NUMBER of tests have been made on the evaporation of tannin solutions in nickel and porcelain basins of different shapes. The evaporation was found to be much more rapid in nickel than in porcelain, and in basins with large diameter and flat bottoms than in those of any other form. The basins were dried in an oven for three hours, cooled for a quarter of an hour, and weighed. The greatest difference in weight between the residues in the porcelain basins was 1 mgrm., whereas the difference between the residues in the porcelain and in the nickel basins was 3—4 mgrms., the latter giving the higher weight. On a second drying for half an hour, all the porcelain basins were found to be of constant weight, but the nickel had lost 1.4 mgrms. From these experiments it was concluded that the porcelain basin, glazed inside and out, with inclined sides and flat bottom and of large diameter (92 mm.) was the most efficient. A second series of tests using glass, aluminium and porcelain basins, again proved the superiority of the porcelain over all the others used.

—H. Br.

Consumption of tanning extracts and barks in U.S.A. in 1908. Bureau of the Census, Washington, D.C., 1909. [T.R.]

Tanning Extracts.

Returns were received in 1908 from 622 works as against 58 in 1907.

PATENTS.

Patent leather or artificial patent leather; Process of making ——. G. R. de Montlord, Boston, Mass. Assignor to The Hyd-leather Mfg. Co., New York. U.S. Pat. 928,235, July 13, 1909.

THIS process consists in preparing a solution of nitro cellulose, a solvent, a vegetable oil, alcohol, glycerol, spirits of turpentine, and a suitable pigment or dyestuff, immersing the leather or fabric in ethyl acetate, coating the surface of a glass plate with one or more layers of the said solution, uniting the leather or fabric with the coating on the glass plate by pressure, then drying the leather or fabric while on the glass plate and finally removing the coated leather or fabric from the glass plate.—T. H. P.

Leather from leather-waste; Process of reconstruction of ——. A. Exbrayat and M. Loup. Fr. Pat. 397,974, Dec. 29, 1908.

THE waste leather is softened by steam and then immersed for 24 hours in ammonia solution, pressed to remove the dissolved tannin, placed in a weak soda solution, and the washed in water. After this treatment, by beating with a hammer or under a percussion press, the waste leather is brought to its natural fibrous state. A further bath of bleaching powder solution bleaches and removes a tannin which may still remain. The substance is then washed, pressed and treated with a solution of albumin and again pressed. After tanning, which may be done with any desired material, the leather is placed in hydraulic press and then glazed. A waterproofing paste may then be applied if desired.—H. Br.

Leather-board; Manufacture of impermeable ——. E. S. Buffum and W. W. Carter. Fr. Pat. 398,199, Dec. 31, 1908. Under Int. Conv., Jan. 2, 1908.

THE pulp containing fibres of tanned hide, is neutralised with a soap solution and a soluble salt of a fatty acid added and the mixture heated and well stirred for about 1 hour. To this mixture, alum, aluminium sulphate, calcium chloride, or copperas (ferrous sulphate) is added which reacts with the soap, forming an insoluble precipitate on the fibres of the pulp. The pulp is then formed into sheets in the usual manner.—H. Br.

Glue and gelatin solutions and solutions of salts; Process of purification of ——. G. B. M. Spigno. Fr. Pat. 397,804, Dec. 22, 1908. Under Int. Conv., Dec. 22, 1907.

THIS process deals with the elimination of lime from glue and gelatin solutions, as well as the recovery of the acid

from solutions of salts, especially those employed in the annery. The glue or gelatin solution is treated with a slight excess of dilute sulphuric acid to decompose insoluble soaps and precipitate lime as calcium sulphate; barium carbonate is then added to precipitate excess of sulphuric acid, and the solution is well mixed. After settling, the solution is decanted or filtered. Where acids such as formic, lactic, or acetic acid have been used as solvents of lime they may be recovered by the above process.

—H. BR.

Glue; Process and apparatus for making colourless —, and for drying aqueous solutions of every kind. J. Lehmann. Fr. Pat. 398,598, Jan. 18, 1909.

By the use of this apparatus prolonged boiling of the gelatinous material is obviated, and a colourless product thus obtained. The finely-divided skin or other material is introduced into the hopper, C, and delivered into a rotatable vessel, A, B, constructed of wire gauze and containing a screw-conveyor, S, attached to the cover at V. This vessel rotates in an outer drum, T, containing water heated by means of steam introduced at v , and the dissolved gelatin passes into this vessel through the wire gauze, whilst the extracted material is conveyed to the outlet at D. The gelatinous solution is then passed, by way of r , through the filter, F, and is pumped into the tank, R, where it is freed from fat. Thence it is delivered into the hopper, m , and falls on to the rotating drying cylinder just below, heated by steam introduced at v' , where it is immediately dried into a thin film. This is detached by the scraper, c , and falls between the longitudinal wings (made of wire gauze) of the rotating cylinder, L, the drying being accelerated by a current of air passing up the chimney, j . The product falls in fine dry flakes at n .—C. A. M.

Glue solutions free from fat; Process for the manufacture of —. Actien-Maschinenbau-Anstalt vorm. Venuloth und Ellenberger and W. Schmidt. Ger. Pat. 211,574, Sept. 25, 1907.

In the preparation of glue solution from bones, by treatment with steam under pressure in closed boilers, the solution produced is led from the boilers into one of two tall, fat-separating vessels, connected at the bottom by a pipe and provided above with pipes for running off the separated fat. By means of suitable pipes and valves, the solution is forced by means of the steam pressure in the boilers, first from one of the tall vessels into the other, and then back again, the separated fat being drawn off from one and from the other vessel alternately, and the operations repeated until no more fat separates. In order to accelerate the separation of the fat, the tall vessels are heated by means of the waste steam from the boilers.—A. S.

Proofing of jute, hemp, &c. Fr. Pat. 398,502. See V.

XVI.—SUGAR, STARCH, GUM, &c.

Asparagus; Two new carbohydrates from —. G. Taurat. Comptes rend., 1909, 149, 48–50.

ASPARAGUS roots were found to contain besides sucrose and invert sugar, two new carbohydrates, *asparagose* and *pseudo-asparagose*. These latter were isolated by a series of fractional precipitations with baryta and alcohol from the aqueous extract of asparagus roots, free from young shoots. Asparagose, $(C_6H_{10}O_5)_n + H_2O$ (n = probably 15 or 16), m.pt. 198° – 200° C., $[\alpha]_D - 35.1^\circ$ when

anhydrous, is tasteless, and when not completely dehydrated acquires a horny condition, as does inulin. It was obtained by the author in fine microscopic needles. It is soluble in 2 parts of cold water, in 340 parts of 95 per cent. alcohol, 103 of 90 per cent., 69 of 80 per cent., 37 of 70 per cent., and in 16 of 60 per cent. alcohol; it is almost insoluble in anhydrous methyl alcohol. It has no reducing action on Fehling's solution, and gives no coloration with iodine. When hydrolysed with acetic acid it yields 93 per cent. of levulose and 7 of dextrose. It is hydrolysed with extreme slowness by invertase, and is destroyed slowly by yeast in presence of a fermentable sugar. It was not found possible to crystallise pseudo-asparagose, which was obtained as a white slightly hygroscopic substance, of specific rotatory power, $[\alpha]_D = 30.3^\circ$, easily soluble in cold water, much more soluble than asparagose, in ethyl alcohol of different concentrations, and soluble in 40 parts of anhydrous methyl alcohol. On hydrolysis it yields 86 per cent. of levulose and 14 of dextrose. It is hydrolysed slowly by invertase. Both asparagose and pseudo-asparagose are present to the extent of 6.7 per cent. in the juice of asparagus roots. The young shoots of asparagus used for culinary purposes do not contain appreciable quantities of these new carbohydrates, which are also absent from the red berries, although present in the green ones.—A. S.

Carbohydrates [starch, glycogen, dextrins]; Colorimetric method for the determination of molecular weights of —.
 II. (Differentiation between primary, secondary and tertiary alcohols). L. Wacker. Ber., 1909, 42, 2675—2680.

In a previous paper (Ber., 1908, 41, 266) the author proposed a method for the determination of the molecular complexity, in terms of hexose groups, of carbohydrates and polysaccharides. The method was based on the development of a red coloration with a strongly alkaline solution of phenylhydrazinesulphonic acid, and the intensity of the colour was ascertained to be constant for equimolecular concentrations of various carbohydrates. This suggests that the chromophoric group is a terminal radical, probably the terminal primary alcoholic group of the chain, since the cyclic alcohol, inositol, does not react. In the present paper the author deals more particularly with starch. The colour standards employed were prepared from $N/1000$ solutions of dextrose or preferably maltose, since it was remarked that the monohexoses give colorations of a slightly bluer tone than the polysaccharides, the results consequently appearing 5—10 per cent. higher. Experiments were first conducted to prove that the starch molecule is not depolymerised by the action of the sodium hydroxide employed. Ordinary starch gave numbers indicating that it is equivalent to 7 hexose groups, but since ordinary starch is a mixture, steps were taken to fractionate it by repeated extraction with boiling water, at a dilution of 1 per 1000. Each fraction was precipitated with alcohol, dried and tested separately; the results indicated: (1), "readily soluble granulose," 5 hexose groups; (2) "less readily soluble granulose," 6; (3), "once decocted starch cellulose," 7; (4), "repeatedly decocted starch cellulose," 8. Erythro-dextrin and achroo-dextrin both gave approximately equal values, viz., 4 hexose groups. Liver-glycogen from different sources showed a molecular complex of 10 hexose groups. For the differentiation between primary and other types of alcohols, $N/100$ solutions of the alcohols and typical standards are prepared, and either 10 or 20 c.c. of each are placed in cylinders and diluted to 100 c.c. A quantity of *p*-phenylhydrazinesulphonic acid is then weighed out, corresponding to 0.4 gm. per test, and is dissolved in sufficient water, with a little sodium hydroxide, to make a solution containing 0.4 gm. per 1 c.c. Each cylinder receives 1 c.c. of the freshly prepared solution, and then 25 c.c. of a 33 per cent. solution of sodium hydroxide are added to each. The contents of the cylinders are stirred every 15 minutes during the first 2—3 hours, and the colours are best observed after 7—8 hours. If the colours are required to keep for several days, 30 c.c. of 33 per cent. sodium hydroxide should be added after the estimation has been made. In the case of carbohydrates a concentration of $N/2000$ gives the best conditions for comparison. Primary alcohols treated in the above manner yield an intense red coloration, whilst secondary and tertiary alcohols show little more colour than a blank, which should always be made up with water under similar conditions. Primary, secondary and tertiary amines also give the same colour reaction, whilst amino-acids, such as glycocoll, give a Bordeaux-red coloration.—J. F. B.

Colloidal starch; Solubilisation of — under the action of alkalis. E. Fouard. Bull. Soc. Chim., 1909, 5, 828—834.

EXPERIMENTS were performed on a perfect solution of soluble starch, containing 25.79 grms. of starch per litre and perfectly neutral (see this J., 1909, 433). Twenty c.c. of this solution were treated in each case with 5 c.c. of potassium hydroxide solution of varying strengths and the mixture poured drop by drop into 250 c.c. of absolute alcohol. By this means the starch was all precipitated together with a quantity of alkali which was constant, for a given strength of the potassium hydroxide solution, if the whole was allowed to stand for some time. By determining the amount of alkali left in the liquid, the amount which was adsorbed by the starch was found. The determinations were made by chemical methods where the concentrations were large; the very low

concentrations were determined by measurements of the electrical conductivity of the solutions. It was found that if the amount of total alkali used, was compared with the amount adsorbed, a typical adsorption curve (hypobolic) was obtained. A similar curve was obtained when the perfect starch solution was replaced by a colloidal solution, but in this case the proportion adsorbed was less. The author comes to the conclusion that no chemical combination takes place and that the starch exhibits no acid functions. Solutions of ammonia and of piperidine are adsorbed to a much lesser extent than potassium hydroxide, by the soluble starch under the same conditions. The author concludes that the action is essentially ionic. The electrical conductivities of the liquids before precipitation with alcohol were also examined and compared with those of the alkali solutions alone. In every case the presence of perfectly soluble starch solution lowered the conductivity of the liquid, but to a much lesser extent in the case of ammonia and of piperidine than when potassium hydroxide solution was used, showing, according to the author, that the association of starch with the metallic ions takes place before coagulation.—E. F.

Starch; Colorations of colloidal and of completely soluble — with a solution of iodine in potassium iodide. M. Castoro. Gaz. chim. ital., 1909, 39, I., 603—607.

By heating chick-pea starch with 2 per cent. sulphuric acid for 5 hours on the water-bath, and filtering, a pseudo-solution is obtained, from which absolute alcohol precipitates white flocks of ordinary soluble starch. This is separated into two portions on treatment with water. The insoluble portion gives a blue-violet colour with iodine solution and corresponds to the amylopectin of Maquenne and Roux (see Gatin-Gruzewska, this J., 1908, 415). The other forms a pseudo-solution which gives an intense blue with iodine. On dialysis, this portion is further divided into a colloidal fraction giving a blue colour with iodine and corresponding to amylose (*loc. cit.*) and a perfectly soluble portion giving a violet colour with iodine. By heating a 5 per cent. potato starch paste with 0.1 per cent. of sulphuric acid for about 1 hour, and filtering, a clear mobile liquid is obtained which is coloured blue, with blue-green reflex, by iodine, and shows distinctly the "Tyndall phenomenon." On dialysis, the diffusible fraction also gives a blue colour with iodine and shows much less sharply the "Tyndall phenomenon"; on standing it becomes opalescent. If the starch paste be heated with 1 per cent. of sulphuric acid, the resulting pseudo-solution filters much more readily. The clear mobile filtrate shows distinctly the "Tyndall phenomenon" and with iodine gives a blue colour, with blue-violet reflex. On dialysis of this pseudo-solution, the diffusible portion gives a violet coloration with iodine. The different colorations of starch solutions with iodine are thus due to difference in the size of the particles in solution or pseudo-solution. Analogous differences are shown by colloidal gold solutions (See also Fouard, this J., 1907, 832; 1908, 238, 631, 1215).—A. S.

Sugar-house and distillery; Process for charging the diffusers used in the —. L. A. Lambert. Fire Addition, dated Mar. 23, 1908, to Fr. Pat. 396,628 Jan. 31, 1908 (this J., 1909, 617).

CLAIM is made for the application of the previously described process to a circular diffusion battery.—L. E.

Saturation contrivances for automatic diffusion, which, by effecting carbonation in the withdrawal cock, eliminate the saturators. C. E. Vallery. Fr. Pat. 397,752, Mar. 1, 1908.

THE liquid and compressed gas are contained in a vessel from which the liquid passes downwards through a series

if perforated, silvered copper discs. These discs are arranged one above another, the perforations of one disc not being directly above those of the next. The discs may be situated in the upper part of the withdrawal cock or elsewhere. The compressed gas from the vessel may be brought into contact with the liquid passing through the perforated discs, by a silvered copper tube passing downwards from the vessel through the centres of the discs; the tube is provided with perforations, so placed, that the compressed gas passes into the spaces between the discs, and saturates the liquid.—L. E.

Sugar; Process for working up residues from the manufacture of cane — A. Wynberg. Fr. Pat. 397,843; Dec. 24, 1908.

Filter press or other residues are reduced to small pieces, dried, and treated with a suitable solvent, such as ether, alcohol, carbon bisulphide, carbon tetrachloride, benzene, etc., whereby wax, or fatty substances, are dissolved, and a residue is left from which the sugar is extracted with water. The colour of the wax left on removing the solvent, varies from greenish-yellow to blackish-brown. The wax is refined and bleached by treatment with nascent chlorine, or with a substance such as fuller's earth, or by successive treatment with both these agents. The wax may be separated into a soft, pale-coloured, saponifiable wax, and a hard, darker-coloured, non-saponifiable wax, by suitable means, e.g., by crystallisation from benzene.—L. E.

Saccharine liquids; Process for purifying [sugar] juices and other — by hydrofluosilicic acid and soluble double fluorides. — L. Rivière. Fr. Pat. 398,063, Dec. 5, 1908. Under Int. Conv., Dec. 7, 1907. (See also this J., 1907, 936; 1908, 584, 702, 869, 1076.)

Diffusion or expressed juice, or other saccharine liquid, treated with hydrofluosilicic acid, or with one or more soluble fluorosilicates, in the state of crystallised salts preferably zinc or magnesium fluorosilicate or both, or with hydrofluosilicic acid and a metallic oxide or carbonate. Potash, soda, and other bases are thrown down, and the gelatinous precipitate also carries down suspended matter; in certain cases, insoluble compounds are formed between the acids combined as salts in the saccharine liquid and the bases of the soluble fluorosilicates. By this preliminary purification, the diffusion juice is rendered less liable to fermentation; it is then worked up in the ordinary way, and, as a result of the preliminary treatment, the proportion of molasses is reduced to a minimum. The following processes for making hydrofluosilicic acid and fluorosilicates are so claimed: A. Decomposition of alkali fluorosilicates by sodium bisulphate. B. Decomposition of native or precipitated calcium fluoride by sodium bisulphate, conversion of the hydrofluoric acid thus formed into hydrofluosilicic acid by addition of silica and finally into soluble fluorosilicates by digesting metallic oxides or carbonates with the hydrofluosilicic acid.—L. E.

XVII.—BREWING, WINES, SPIRITS, &c.

East juice; The role of the enzymes in — E. Buchner and H. Haehn. Biochem. Zeits., 1909, 19, 191—218.

Fresh yeast juice rapidly loses its power of fermenting sugar when kept. This has been ascribed to the influence of the endoptyptase which has been shown to be present in the juice, but it is unlikely that two enzymes present in a cell should be mutually inimical. Harden and Young (this J., 1908, 824) have shown that for fermentation to occur the zymase, the presence of a so-called co-enzyme is necessary. Yeast juice can be divided by dialysis by filtration through a gelatin filter into a residue and a filtrate, both separately inactive, but when combined capable of producing fermentation. The inactive residue can also be activated by addition of boiled east juice, which is similarly able to revive a juice which has lost its fermentative power by continued action on sugar. The co-enzyme appears to be an organic phosphoric acid compound not precipitable

by magnesia mixture, and destroyed by ignition, or by lipase; lecithin produces results similar in many respects to those yielded by the boiled juice. The authors show that the revivification of a yeast juice by boiled juice is not without limits. If the addition is made three days after the beginning of fermentation, the gas generated is always in notable amount, but if added only a day later, the juice often produces little or no effect. This is due to the fact that the co-enzyme originally present having been destroyed, its protective action is removed and the endoptyptase destroys the enzyme, which in consequence cannot be revived by further additions of boiled juice. Yeast juice stored at 22° C. without sugar, loses its power of being revived by boiled juice much earlier than if sugar had been present, which shows that the reduction of power occurring in the juice from day to day is not connected with the fermentation it may have produced. By studying the influence of additions of glycerin, disodium phosphate, and potassium carbonate, it has been sought to decide whether the co-enzyme really does disappear as the fermentative power of the juice decreases. In agreement with the old observations of Wittich and Hüfner on the preservation of enzymes, addition of glycerin was found to maintain the activity of stored juice for one or two days, after which it could be further stimulated by addition of boiled juice. Addition of 5 per cent. of disodium phosphate acted very beneficially in maintaining, or regenerating, the fermentative power, apparently protecting the zymase from the action of the endoptyptase by its slight alkalinity and also restraining the destruction of the co-enzyme by its phosphoric acid content. Potassium carbonate, in 2.5 per cent. strength, protects the zymase, so that revivification of a juice preserved with it, is always very marked, but it destroys the co-enzyme. Buchner and Klatte (Biochem. Zeits., 1908, 8, 533; and this J., 1908, 515), showed that a juice could be kept active for two or three weeks by repeated additions of sugar and boiled juice; the authors now show that a similar result can be obtained by repeated addition of boiled juice only. It thus appears that the co-enzyme shields the zymase from the action of the proteolytic enzyme, but is itself destroyed by some other agency, as digestion with trypsin does not destroy the revivifying action of a boiled juice. On the other hand, the power of the boiled juice is much reduced by the action of lipase, by standing with 2.5 per cent. potassium carbonate solution, and even by repeatedly boiling, all of which agrees with the assumption that the active substance is a readily hydrolysable organic phosphoric acid ester, and, as it can be readily precipitated from a boiled juice by alcohol, endeavours will be made to isolate such a compound.—R. L. S.

Top-fermentation systems; Technical and commercial points of [German] — F. Schönfeld. Woch. f. Brau., 1909, 26, 352—353.

In Germany two systems are in vogue in the top-fermentation breweries: the tun system and the cask system. The tun system affords a better working up of the yeast and a more complete purging of the beer; the latter clears more rapidly, leaves less deposit, and suffers less waste. In the cask system the yeast tends to fall back again when it works up to the top of the cask, and more remains in the beer to be separated by sedimentation, causing greater loss in racking. The smaller the casks the greater is the waste, and the cleansing of the beer is made more difficult by the necessity of frequently filling up the cask with beer already cleansed, in order that the yeast may work its way out of the bung hole. Tun fermentation can be carried out at a lower temperature than cask fermentation, since the resistance offered by the walls of the cask cannot be overcome at low temperatures. The oxygen-requirements of the yeast are not fully satisfied by the air entering the narrow bung-hole; the fermentation therefore tends to be sluggish and the crop of yeast a poor one. Besides providing for a high fermentation temperature in cask fermentation, it is also desirable to give a powerful aëration before fermentation sets in. This is best done by pitching the yeast in a tun and racking over into casks only shortly before the yeast begins to work up; the operation of racking aërates the beer. Other conditions

being equal, attenuation tends to go further in cask fermentation, than in tun fermentation. In tun fermentation it is possible to fractionate the yeasts of different fermentative capacities and physiological qualities, whereas this is impossible in cask fermentation, the whole mixture of all kinds of yeasts in all stages of maturity being expelled bodily together with the beer. In certain small breweries with irregular turn-over, the cask system may be advantageous, provided the casks are lacquered internally and fitted with some arrangement for catching the yeast at the bung-hole. In the case of certain beers, e.g., Berlin "Weissbier," it is absolutely essential to use the tun system, because these throw up a sticky scum of impurities, which must be removed by skimming.—J. F. B.

Fermentation; Pure — by a continuous process in closed steel tanks. P. Martens. Z. ges. Brauw., 1909, 32, 372—373.

Is the "Yeasting Forward System," recently introduced in America, the fermenting vessels consist of closed steel tanks, which are best of such size that one is capable of holding the whole of a brew. The sterile wort is run into the first of these tanks, in which it is pitched with a considerable quantity of yeast. While the wort is running in, it is aerated by means of an aerating cock, this aeration being repeated the next day. When the first head has formed on the wort—this occupies about 24 hours—the tank is connected by means of a hose with the second tank, into which one-half of the fermenting wort is allowed to pass. The second brew is then divided equally between these two tanks, the contents of the first being allowed to ferment to an end. On the next day, one-half of the contents of the second tank is introduced into a third tank, and so on. While the head is forming and for one day after it has formed, a three-way cock at the upper part of the tank is so arranged that the carbon dioxide passes into the air. But when all the air has been displaced from the tank, the carbon dioxide is drawn off, compressed and used for carbonation. During the whole fermentation, however, care is taken that a slight excess pressure prevails in the fermenting vessel. On the last day of the fermentation, a current of air is passed over the surface of the beer, the effect of this being that the yeast settles rapidly and compactly to the bottom of the vessel. This system is rapid, keeps the yeast almost pure and admits of the use of fermenting vessels of almost any size. Further, it effects a saving in labour.—T. H. P.

Stouts; The presence of yeasts which produce secondary fermentation in English and German — F. Schönfeld and J. Dehnicke. Woch. f. Brau., 1909, 26, 365—368, 377—379.

THE authors have examined a number of English and German bottled stouts and confirm the statements of van Laer, Claussen, and others, that English stout contains large numbers of secondary-fermentation yeasts which, when added to dark beers, produce a characteristic taste and odour of stout in the same. On the other hand, these yeasts were not found in German stouts, although other wild yeasts were found which to some extent gave a characteristic taste to the beverage. It appears that, whilst certain of the *Torula* species produce the best stout, other "wild" yeasts are capable of forming aromatic substances, though to a less extent than the former.—W. P. S.

Yeast after fermentation; The life of — E. Kayser and A. Demolon. Comptes rend., 1909, 149, 152—155.

IN the preparation of fermented beverages the yeast is not to be regarded merely as an agent for producing alcohol, intracellular reactions also intervene, resulting from the complex vital activities of the cells, which reactions may continue after the complete disappearance of the sugar. For instance, in practice, certain white wines which clarify badly may be treated successfully by leaving them in contact with coarse lees from December until the spring. The authors have previously shown that prolonged contact with the lees is accompanied by

phenomena of oxidation, attributable to the yeast and depending on the degree of aeration. They have now studied the influence of temperature, variety of yeast, life-history and nitrogenous nutrition of the yeast on the phenomena previously observed. They have worked with sterile, filtered wines, and yeast previously cultivated under aseptic conditions, the observations extending over a period of six months. In all cases a disappearance of alcohol was recorded quite apart from that due to evaporation, and particularly large when free access of air was allowed. It is definitely established that the yeast is capable of attacking the alcohol after fermentation. In some cases the production of aldehyde is remarkably large, this reaction being even capable of taking place at temperatures near 0°C. The previous history of the yeast and its nitrogenous nutrition play an important part in its activity after fermentation. The total acidity of the wine also decreases owing to the destruction of the fixed acids, and since this happens without exposure to air, it must be concluded that these acids are assimilable by yeast in absence of sugar. The changes in the furfural content suggest that the yeast plays a part in its formation, probably as the result of nitrogenous metabolism. The ethers and higher alcohols undergo very little change. The difference between the ordinary yeasts and the definitely alcohol-consuming yeasts is only one of degree.—J. F. B.

Ciders; Action of ultra-violet rays on fermenting — Maurain and Warcollier. Comptes rend., 1909, 149, 155—156.

THE authors have observed that exposure to the ultra-violet rays is capable of arresting the fermentation of cider. The cider itself absorbs the rays very largely, and in order to arrest the fermentation, it is necessary to make the exposure in very thin layers, or else to dilute the cider considerably. The source of the rays used, was a mercury-vapour lamp of quartz and the specimens were exposed in quartz cells. When the cider was exposed in layers of about 0.25 mm., a time of exposure of about 3 minutes was sufficient to arrest fermentation; in layers of 1 mm. in thickness, the absorption of the rays by the liquid was sufficiently great to prevent their action on the yeast furthest removed from the source of light. With cider diluted 20 times with water, an exposure of 1—2 minutes was sufficient to arrest fermentation in layers 1.75 mm. thick.—J. F. B.

Jamaica rum; Studies of fermentations in manufacture of — S. F. Ashby. Int. Sugar J., 1909, 11, 243—251, 300—307.

TWO types of yeast—budding yeasts and fission yeasts—can be isolated from rum washes. The budding yeasts ferment more rapidly than the fission yeasts, but they are far more sensitive to acids. Of the three common distillery acids, lactic acid is the least inhibitive, acetic acid is more so, and butyric acid is decidedly poisonous. Budding yeasts, on account of their greater activity, may predominate in liquids of low acidity, but the fission yeasts are practically always the fermentation agents in ordinary sugar-estate washes, which are generally too acid for the former type. Some of the fission yeasts possess bottom-fermentation characters, whilst others are top-fermentation yeasts. None of these yeasts is capable of developing the flavour of rum on its own account, the flavouring ethers (esters) being produced by the long contact of the alcohol with the acids of the wash, but the top fermentation yeast, owing to its slower action, prolongs this contact and thus favours the production of ethers (esters) and gives a better rum. The bottom yeast is a more rapid worker than the top yeast, giving an advantage of 2—3 days in the fermentation period; it gives a rapid and uniform main fermentation, but the wash "dies" slowly. The top yeast shows a uniform fermentation throughout, lasting for 7—9 days, during which 16—18 per cent. of proof spirit is produced. Washes containing up to 16 per cent. of sugar may be fermented in a reasonable time; stronger washes are uneconomical owing to sluggish fermentations. The yeasts attenuate about equally, but the bottom yeast gives a better yield

alcohol, because the yeast-crop is less. Owing to the exposure of the top-fermentation yeast to the air, it produces a far larger crop, and more sugar is consumed in the work of reproduction. The top-fermentation yeast leaves less unfermented sugar in the wash. The bottom yeast is capable of producing 25 per cent. of proof spirit in the presence of an excess of sugar, as against 23 per cent. for the top yeast; it also shows the injurious effect of alcohol at a higher concentration than the top yeast, i.e., 18 per cent. of proof spirit, as against 16 per cent. indications were obtained to the effect that the bottom yeast is probably unstable in type, and when kept in the presence of fermented wash, is liable to change over to the top-fermentation type. When molasses is stored for some weeks, it is liable to undergo spontaneous fermentation and a serious loss of sugar is liable to occur. The author has isolated the active agent of this fermentation in the form of a *Torula*, which is capable of fermenting only the invert sugar of strong molasses. Its activity is best checked by liming the molasses at the rate of 6 lb. for 100 gallons, the lime being added in the form of a milk with a minimum quantity of water. The author is also studying the "fruit ether" yeast of molasses; it works very slowly, washes set up with it fermenting in periods of up to 27 days. The yeast apparently produces both alcohol and acetic acid, but the increase of acid is low; the esterification, therefore, is probably in close relation with the vital activity of the yeast.

PATENTS.

Kwass"; *Process for the production of* —. A. Eisenberg, St. Petersburg. Eng. Pat. 20,978, Oct. 5, 1908.

MASH is prepared at a temperature of from 45° to 70° C. from malted barley or rye, or from potato starch to which about 10 per cent. of malt has been added. When complete inversion of the starch has taken place, the mash is strained, boiled, cooled, and allowed to settle. The liquid is then drawn off, fermented by the addition of activated yeast, and, when the desired quantity of alcohol has been produced, the yeast cells are removed by suitable means. The liquid is next inoculated with organisms which produce lactic acid fermentation, and finally filtered into receptacles containing proportionate quantities of sugar syrup or honey and spice.—W. P. S.

Wine fermentation; Apparatus for — and decantation of sparkling wines under pressure. E. Charmat, Paris. U.S. Pat. 927,944, July 13, 1909.

In combination with apparatus for bottling effervescent liquids, an apparatus is arranged adapted to maintain uniform gaseous pressure, comprising fermentation receptacles, a pasteurising apparatus, cooling and decanting apparatus, a source of carbon dioxide or other inert gas, a "dosing" apparatus, a storage receptacle and a system of pipes arranged and combined to serve for the circulation of the wine through the apparatus and the inter-connection of the parts under gas pressure for the purpose of maintaining the same uniform throughout the apparatus; a system of pipes for the circulation of steam for pasteurising and for cleansing the interior of the vessels and pipes; a system of pipes for the circulation of a refrigerating medium through the cooling and decanting apparatus; an air inlet filter, the whole so combined that the fermentation receptacles are in communication with the atmosphere through the filter, whilst the remainder of the apparatus is in a closed cycle adapted to maintain the effervescent liquid under uniform gas pressure throughout.—T. H. P.

Vinegar; Process of making —. W. Antoni, Lodi, Cal. U.S. Pat. 928,578, July 20, 1909.

WINE, cider, or the like is subjected to partial distillation, at the ordinary or diminished pressure, the distillate being acetified by the quick process and the residue by the action of an acetified distillate. The two acetified liquids are then mixed.—T. H. P.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Nitrogen-free extractive matter in fodders and foodstuffs. J. König and W. Sutthoff. Landw. Vers.-Stat., 1909, 70, 343—403. Chem. Zentr., 1909, 2, 304—305.

THE nitrogen-free extractive matter of fodders and foodstuffs comprises carbohydrates of different kinds, acids, colouring matters, bitter principles, pectin substances, and methylated and acetylated compounds. Methods are available for the quantitative determination of the acids, the carbohydrates soluble in cold water, the pentosans together with the hemicelluloses soluble in dilute acids, and the cellulose, together with the accompanying cutin. The different methods which have been proposed for the determination of starch yield widely varying results. Mayrhofer's direct method is probably the most accurate, but is not always applicable. The inversion process, based on the use of steam under pressure, or of dilute acids, and determination of the sugar produced (allowance being made for the pentoses also formed) yields more accurate results than the fermentation process. Lintner's polarisation process yields good results even with materials poor in starch. The nitrogen-free extractive matter also contains not inconsiderable quantities of substances which cannot at present be determined and the nature of which is unknown, although from their high carbon content, they may probably be grouped with the "lignins." These substances with a higher carbon content than carbohydrates behave in a similar manner to the hemicelluloses. They are insoluble in cold water, but partially dissolve when treated with steam under pressure, or with dilute acids, e.g., the glycerin-sulphuric acid reagent of König. The portion soluble in water under pressure has a lower carbon-content than that soluble in glycerin-sulphuric acid, the carbon content of the latter portion being slightly higher than that of the lignin in the "crude fibre." The digestibility of the substances dissolved by glycerin-sulphuric acid is always less than, or equal to, but never greater than that of the insoluble "crude fibre." The authors' results show that analysis as performed at present, gives no insight into the actual content of "lignins," if this term be used to designate compounds containing more than 45.5 per cent. of carbon. Apparently the substances rich in carbon ("lignins") are present in different stages of condensation, in a manner analogous to the hexoses (dextrin, starch, hemihexosans, and cellulose-hexosan). The carbon-content of the digested "total nitrogen-free extractive matter" is uniformly higher than that of the digested nitrogen-free "crude fibre," of which relatively more cellulose than lignin is digested. Since the carbon-content of the digested "total nitrogen-free extractive matter" is also higher than that of carbohydrates (up to 45.5 per cent. for pentosans), the term "carbohydrates" would not be justified for this portion of fodders and foodstuffs rich in "crude fibre," whilst the name "nitrogen-free extractive matter" is a misleading description of substances which are not readily soluble. It is suggested that for the present the name "other nitrogen-free substances" be adopted.—A. S.

Birch-juice; Composition of —. W. Lenz. Ber. deutsch. pharm. Ges., 1909, 19, 332—343.

THE Birch-water obtained by tapping the trees (50 of which yield about 175 kilos. of juice in 4 days) is mixed with dextrose and milk of almonds and fermented into

birch-wine. The following table gives analytical results obtained with three commercial samples of the juice, and with a specimen obtained directly from the trees:—

	Sp. gr. at 15° C.	N/10 KOH required to neutralise 100 c.c.	Total solids in 100 c.c.	Ash.	Reducing sugars.
		c.c.	grms.	grms.	grms.
Commercial juice (Hamburg)	1.0220	20.08	0.4960	0.041	0.0269
Do. with addition of alcohol	(0.9926)	25.49	0.3088	0.033	0.0323
Commercial juice (Harz) with addition of alcohol ..	(0.9947)	22.35	0.2540	0.039	0.0135
Juice from trees	1.0071	7.00	1.6760	0.036	1.5400

The last of the above ("Juice from the trees") was obtained directly, in the spring of the present year. The remaining three were juices of 1908.

The sugar consisted in the main if not entirely of levulose. In each case large quantities of malates (notably calcium malate) were found, but oxalic, citric and tartaric acids were absent. The ash was characterised by the large excess of basic constituents. Thus, the ash of the fourth sample after being warmed with *N/10* sulphuric acid, the excess of which was titrated back, showed an alkalinity corresponding to 58.1 per cent. of potassium carbonate.

—C. A. M.

Protein substances; Hydrolysis of — by means of hydrofluoric acid. L. Hugonin and A. Morel. *Comptes rend.*, 1909, 149, 41—43.

HYDROFLUORIC acid behaves differently in its hydrolytic action upon proteins of different origin and of different degrees of resistance to its action. Thus in the case of substances, such as gelatin, which have been modified by boiling, complete hydrolysis is effected by a 15 per cent. solution of hydrofluoric acid, the products consisting of amino-acids. With stronger acid (20 to 30 per cent.) amino acids are still liberated, but are accompanied by di- and tripeptides. At a concentration of 35 per cent. of hydrofluoric acid, the products of hydrolysis include only a small proportion of amino-acids, for the polypeptides formed resist the further action of the acid, though they can be decomposed by a more profound hydrolysis. One of them yielded the following products: Arginine, lysine, phenylalanine, alanine, and glycocoll. At a concentration of 45 per cent. of acid, free diamines are no longer obtained, even after long-continued heating. Further experiments have shown that hydrofluoric acid in solutions of a concentration to liberate these peptides, does not effect the condensation of free amino-acids. In the author's opinion the peptides represent natural complexes pre-existing in the protein molecule. Some of them can be obtained as crystalline compounds (nitrates, picrates). Hydrofluoric acid may be used as a reagent which will show the presence not only of free amino-acids or their compounds, but also of other constituents belonging to the series of amino derivatives of the sugar group, some of which are reducing and others non-reducing substances. By the use of hydrofluoric acid at a suitable concentration proteins may be gradually hydrolysed on the boiling water-bath so as to yield a series of products in different stages of hydrolysis.—C. A. M.

Paraffin wax in lard; Rapid sorting-test for the detection of —. H. S. Shrewsbury. *Analyst*, 1909, 34, 348.

FIVE grms. of the melted lard are saponified with 20 c.c. of a reagent prepared by dissolving 453 grms. of sodium hydroxide in 1 litre of water and adding 500 c.c. of glycerol. The hot product of the saponification is dissolved in 50 c.c. of industrial (non-mineralised) methylated spirit, added drop by drop, and the appearance of the cooled solution is observed. Pure lard gives a clear solution, whilst in presence of as little as 2 per cent. of paraffin wax, opaque flocks are observed. After some time the solution sets to a slightly opalescent, but homogeneous jelly in the case of pure lard, but if 2 per cent. of paraffin wax be present, the opaque flocks impart a very characteristic cloudy appearance to the jelly.—A. S.

Enzymes and anti-enzymes. [Milk, etc.] A. J. J. Vandevelde. *Bull. Soc. Chim. Belg.*, 1909, 23, 288.

ADDITION of a solution of iodoform in acetone prevents all bacterial development in physiological media but does not

affect enzyme activity. The study of the autolysis of milk and of certain serums shows that when these are subjected to a preliminary heating for half an hour at 55° C.,

the proteolytic properties are increased. This behaviour is explained as due to the destruction of an anti-enzyme by heat, so that the action of the enzyme, having nothing to oppose it, is increased.—E. F. A.

Casinate; Refractive indices of solutions of the —, and the acid and alkali equivalents of casein. T. B. Robertson. *J. Physical Chem.*, 1909, 13, 469—489.

THE author's researches have led to the following conclusions: The difference between the refractive indices of two solutions of caseinate, which differ only in their casein content, is proportional to the difference between the percentages of casein which they contain. This relation may be expressed by the formula: $n - n_1 = a \times c$, where n = the observed refractive index of the solution, c = the percentage of casein which it contains, n_1 = a constant depending on the nature and concentration of the substance employed to dissolve the casein, and a = a constant numerically equal to the change in the refractive index of the solvent caused by the introduction of 1 gm. of casein to 100 c.c. By means of this formula the concentration of casein in a solution can be very accurately determined, the error rarely exceeding 2 per cent. of the quantity of casein in 100 c.c. The change in the refractive index of a solution of a base, which is caused by the introduction of casein is independent of the concentration and nature of the base; if the volume of solution be 100 c.c. and the weight of casein 1 gm., the change in the refractive index is 0.00152. The same constant holds for solutions of hydrochloric acid, so that whether the casein be acting as an acid or as a base, its effect on the refractive index of the solution is the same. The difference between a solution of sodium caseinate and that of water at the same temperature, is independent of the temperature between 20° and 40° C. The hydrochloric acid equivalent of casein (i.e., the quantity of acid required to just dissolve 1 gm. of casein) has been determined by the author. For solutions containing 1.25 per cent. of casein, it was found that 1 gm. of casein = approximately 32×10^{-5} equivalent-grm. of hydrochloric acid. Casein dissolves in alkaline solutions rapidly at first and later, more slowly. After the point of neutrality to litmus has been reached, additional casein only dissolves with extreme slowness; the neutral point to litmus is not, however, the limit of solubility. The sodium hydroxide equivalent of casein has been determined for solutions containing 2 per cent. of casein, and it was found that 1 gm. of casein, at "saturation" of the base, = 11.4×10^{-5} equivalent-grm. mols. of sodium hydroxide. The lithium hydroxide equivalent was the same. The acidity of solutions of bases "saturated" with casein was determined by means of indicators and was found to lie between 10^{-5} and 10^{-6} NH⁺; the hydroxyl concentration in these solutions, therefore, lies between 10^{-9} and 10^{-8} N. —J. Pure Food Act (1908), in New South Wales. Bd. of Tr. J., July 27, 1909. [T.R.]

THE "Pure Food Act, 1908," came into force in New South Wales on July 1st, 1909.

The Act provides, *inter alia*, that no person may sell any article of food or any drug which is adulterated or falsified.

scribed, or which is packed or enclosed for sale in any manner contrary to the provisions of the Act, or any food or drug mixed with other materials whereby such food, &c., is rendered dangerous or injurious to health or whereby its quality or potency is injuriously affected.

The Governor may, by notification in the "Gazette," prohibit the advertising or sale of any food or drug or appliance which is injurious to life or health, or which by reason of its inactivity or inefficiency is useless for the advertised purposes of cure.

The sale of any substance or compound as a disinfectant, germicide, antiseptic or preservative may also be prohibited.

The Act, which also provides for the inspection and analysis of foods, &c., may be seen by persons interested in application at the Commercial Intelligence Branch of the Board of Trade, 73, Basinghall Street, London, E.C.

PATENTS.

Milk; Preparation of coagulated —. S. Slavoff, Kezanlik, Southern Bulgaria. Eng. Pat. 14,249, July 4, 1908.

FRESH, boiled, or pasteurised milk is coagulated by means of a pure culture of *streptococcus bulgaricus acidus lactis*, which has been separated from the other species of micro-organisms in ordinary coagulated milk. A separate strain is made for maintaining the temperature at 35° to 45° C. during the coagulation. It is stated that coagulated milk thus prepared will keep 40 to 50 days in a fresh condition.—C. A. M.

Desiccating apparatus [for milk]. J. Roeh, Assignor to Crystallised Milk Co., Spokane, Wash. U.S. Pat. 927,169, July 6, 1909.

THE liquid (milk) to be desiccated, is delivered on to the surface of a heated rotating drum, the temperature of which can be varied at will, from a spraying device attached to the feed tank which is caused to move to and fro in a direction parallel to the axis of rotation of the drum.—W. H. C.

Cereal products. J. H. Quine, Rochester, New York. Eng. Pat. 15,474, July 21, 1908. Under Int. Conv., July 29, 1907.

GRAIN is made for a process of treating bran, in order to recover the mineral constituents for admixture with ordinary flour, &c. The bran is treated with water to extract soluble salts, and the residue then treated with an acid solvent (e.g., hydrochloric acid) and water, and subsequently with an alkaline (sodium hydroxide) solution of sufficient strength to extract gluten, &c. but not to dissolve cellulose. The acid and alkali in the second and third extracts are neutralised, and the whole of the extracts are united and evaporated to dryness, preferably *in vacuo*, and the residue reduced to a powder.—C. A. M.

Flour or ground cereals; Process for treating —, [increasing the water-binding capacity]. A. Waldmeyer, Zürich, Switzerland. Eng. Pat. 24,425, Nov. 13, 1908.

THE flour is heated to a temperature between 70° and 100° C., and a current of air is meanwhile passed over it, the temperature giving the best result varies, and must be determined for each batch of flour treated. (Reference is directed to Eng. Pats. 3469 of 1880, 11,466 of 1904, and 15,597 of 1905; see this J., 1908, 862).—W. P. S.

Beetroot flour; Production of —. L. Dautrebande, Daussoulx, Belgium. Eng. Pat. 1074, Jan. 15, 1909.

THE beetroots are washed and placed in a drying chamber at a temperature which is raised gradually from 36° to 60° C. When the beetroots have lost about 10 per cent. of their weight, they are removed from the chamber, sliced, and the slices are further dried in a current of air, first at a temperature of about 70° C. and then at 90° C. Finally, the dry slices are ground. If a brown flour be desired, the flour is again placed in the hot-air oven.

—W. P. S.

Keratin; Process of producing digestible substances from —. C. Neuberg, Charlottenburg, Germany. U.S. Pat. 926,999, July 6, 1909.

KERATIN or keratin substances are converted into digestible albumoses and peptones containing sulphur, by treatment with dilute mineral acids at a moderate temperature. The reaction is at an end when a diluted sample of the liquid, which has been treated with phosphotungstic acid or other reagent for albumoses, and filtered, is free from any considerable quantity of amino-acid. The albumoses and peptones formed in the main portion of the liquid are then at once isolated.—A. G. L.

Fat; Process for the manufacture of an edible —. S. Rigaut. Fr. Pat. 398,241, Mar. 18, 1908.

FROM 40 to 70 parts of cocoanut oil, 15 to 40 parts of stearine, and 15 to 25 parts of oil or lard are melted together and emulsified with about 10 parts of milk, or milk and water. The emulsion is then cooled, and again mixed. Substances such as lecithin, lactose, &c. may be added, and the oil employed may consist of any suitable vegetable oil. The oil and fat may be bleached previously, if desired.—W. P. S.

(B.)—SANITATION; WATER PURIFICATION.

Water; Detection of very small quantities of sodium carbonate in —. J. Flamand. Bull. Soc. Chim. Belg., 1909, 23, 296—299.

THE ordinary method of expressing the results of the analysis of the dissolved salts in water in terms of magnesium and calcium carbonate, calcium and sodium sulphate, and sodium chloride, does not indicate a further possible content of sodium carbonate, the presence of which is indicated by the appearance of a red coloration when the water is boiled with hops. These small quantities of alkali carbonates may be estimated by the method described by Seyffert (this J., 1908, 515).—E. F. A.

PATENTS.

Water; Process for the purification of —. G. Lambert. Third Addition, dated Jan. 6, 1909, to Fr. Pat. 361,435, May 3, 1905 (this J., 1906, 862, 1063; 1907, 888).

MANGANOUS phosphate, $Mn(PO_3H_2)_2 \cdot 2H_2O$, may be used in place of the manganese sulphate recommended in the original specification. Its use enables a treated water to be obtained which is quite free from manganese salts.—W. P. S.

Manufacture of ferric sulphate and making same up with more or less waste products to produce cakes or slabs [for sewage treatment]. Eng. Pats. 15,239 and 17,976, See VII.

(C.)—DISINFECTANTS.

Disinfectants; Principles involved in standardising —, and the influence of organic matter on germicidal value. H. Chick and C. J. Martin. Journal of Hygiene, 1908, 8, 634—697.

A DISINFECTANT varies in efficiency with regard to organisms, as much as ten times, according to the organism tested. For spores, metallic salts rank highest as germicides. The action of phenol and emulsified disinfectants on spores, is too feeble for practical consideration. A virulent type of any particular species is as a rule more difficult to kill than a non-virulent type. With mercuric chloride the reduction caused by blood serum is much greater than with phenol. The presence of finely divided organic matter—animal charcoal, dust, bacteria, faeces, etc.—affects the germicidal value of emulsified disinfectants containing tar acids, in a much greater degree than that of solutions of phenol. The tar acids can be removed by the addition of any of the finely divided forms of organic matter just referred to. Three per cent. of finely divided powder of dried faeces in suspension had the effect of reducing the efficiency of phenol to the extent of about 10 per cent., and of commercial cresols from about 30 to 50 per cent.

Electrolytic disinfectant. F. W. Alexander. Annual Report for 1908 of Medical Officer of Health for the Metropolitan Borough of Poplar. 80—84.

THE plant for the preparation of a disinfecting fluid containing magnesium hypochlorite (see this J., 1906, 1102; 1908, 158) has now been in operation for 3 years; in 8 hours 185 gallons of solution containing 4.5—5 grms. of available chlorine per litre are produced. During 1908, the cost of repairs, renewals, and improvements for the whole installation was less than £45. 28,280 gallons of the solution were manufactured, the total cost (excluding labour) being £56 2s. 5d., made up as follows:—Electricity, 4543 units at 1½d. per unit, £28 7s. 10d.; magnesium chloride, 47 cwt. 3 qrs. 10 lb., £10 9s. 3d.; salt, 6 tons, £9 18s.; caustic soda, £5 17s. 4d.; water, £1 10s. In the past 3 years, 60,000 gallons of the solution have been manufactured at a total cost for electricity and materials of about £120, and 12 zinc electrodes have been replaced at a cost of less than £2. A sample of the solution which contained 4.818 grms. of available chlorine per litre on March 27, 1906, contained 3.785 grms. after keeping till Oct. 29, 1908. According to a report by Klein, 1 oz. of the fluid to 150 oz. of water will kill the cholera germ in 2½ mins., and will also kill the typhoid bacillus. In referring to the financial aspect, it is stated that in the 3 years the plant has been working, it has paid for itself and also for the construction of the depot where it is installed, and has also resulted in a saving of over £1200 to the Borough.—A. S.

Disinfectant. "Keramyli." E. Prior. Allgem. Z. Bierbrau. n. Malzfabrik., 1909, 37, 354—355.

"KERAMYL" consists of an aqueous solution of commercial hydrofluosilicic acid, the sample examined by the author containing 26.01 per cent. of the acid and small proportions of silicic and sulphuric acids, ferric oxide, alumina, lime, and alkalis. In 2 per cent. solution, keramyli exerts a vigorous solvent action on iron and zinc and a somewhat less, but still appreciable action on tin; copper and brass, on the other hand, are only slightly attacked. Experiments with *Sacch. Froberg*, *Mycoderma cerevisiae*, *Bact. acetii*, *Bact. fluoresc. liquef.*, *Oidium lactis* and *Pentacillium glaucum* show that a 1 per cent. solution of keramyli destroys these organisms in 12 hours, whilst, with a 2 per cent. solution, 4 hours is sufficient. Strongly infected rubber hose and filtering material were also disinfected in 4 hours by a 2 per cent. solution of keramyli.—T. H. P.

PATENTS.

Sheep dips for disinfecting, &c.; Manufacture of cleansing fluids for use as —. W. G. Little, East Grinstead, and H. Morris, Doncaster. Eng. Pat. 16,982, Aug. 12, 1908. Addition to Eng. Pat. 26,608, Dec. 2, 1907 (this J., 1908, 587).

A MORE or less solid compound may be produced by mixing 85 parts of coal tar creosote, 15 parts of sulphonated (but not neutralised) castor oil, and 6.5 parts of saturated sodium hydroxide solution, the quantity of alkali added being sufficient to neutralise the sulphonated oil. The mixture is heated to boiling and then allowed to cool. When stirred with water the compound produces an emulsion suitable for the purposes in question.—W. P. S.

Vines, &c.; Insecticide for use on —. Soc. Chimique des Usines du Rhône (ancien. Gilliard, P. Monnet et Cartier). Fr. Pat. 398,281, Mar. 19, 1908.

A SOLUTION, containing from 500 to 1000 grms. of copper salicylate per 100 litres, is employed for the purpose. The copper salicylate may be prepared by mixing copper sulphate solution with calcium salicylate solution; barium or sodium salicylate can be used in place of the calcium salt.—W. P. S.

XIX.—PAPER, PASTEBOARD, &c.

Sulphite wood pulp; Determination of resin in —. A. Steinschneider. Z. angew. Chem., 1909, 22, 1410—1411. THE author confirms the fact recorded by Opfermann (this J., 1909, 324) that the amount of resin extracted

from a pulp by alcohol is always greater than that extracted by ether under the same conditions. Working with a highly resinous pulp prepared from waste wood, he found, after 5 hours' extraction, 1.15 per cent. of resin with ether, and 1.54 per cent. with alcohol. Further, whereas a more prolonged extraction with ether yielded no increased quantity of resin, the quantity extracted by alcohol increased as the time of extraction was extended, and amounted to 1.84 per cent. with 20 hours' extraction. According to the author the extracts obtained by means of the two solvents are identical in their nature, and possess nearly identical constants. For the determination of the absolute resin contents of a pulp, a very prolonged extraction with alcohol is certainly more accurate than the ether method, but the latter is far more rapid and convenient for comparative purposes. The difference in the results obtained by the two methods is attributed to the higher temperature which is obtained when alcohol is used in the Soxhlet apparatus.—J. F. B.

Paper trade of Argentina. Bd. of Tr. J., July 29, 1909. [T.R.]

THE following particulars respecting the position of the paper trade of Argentina have been received from H.M. Consul at Buenos Aires:

The values of the imports of paper and paper manufactures in each of the last five years were as follows:—

	Paper and Cardboard.	Paper Manufactures.	Total.
	£	£	£
1904.....	463,000	335,000	798,000
1905.....	451,000	369,000	820,000
1906.....	569,000	406,000	975,000
1907.....	693,000	438,000	1,131,000
1908.....	652,000	527,000	1,179,000

The value of the import trade has increased from 4,000,000 dols. gold in 1904 to 6,000,000 dols. in 1908. The most important item in the trade is that of paper in rolls for newspapers. The quantity of this imported has risen in five years from 6,400 tons to 12,200 tons, and there is every probability of a further increase. In the city of Buenos Aires alone there are published about 50 daily papers, with a daily circulation of a quarter of a million. The total number of newspapers, reviews, and other periodicals published in the Republic has been estimated at from 400 to 500.

The United States of America and Germany supply the bulk of the paper imported. The imports from the Dominion of Canada, however, increased from 125 tons in 1904 to 577 tons in 1907.

The item next in importance is that of cardboard, the importation of which is almost monopolised by Germany and Holland. The United Kingdom supplies only a very small amount, and that is much less than was furnished in 1904.

With the one exception of cigarette paper, British goods appear among all the classes of paper material imported. It is, however, only in a few lines, such as toilet and photographic papers, lithographic and blank books that they are supplied to any considerable extent.

Local products.—There are four paper factories in the city of Buenos Aires and six in the Province. These have a share capital of 7,000,000 dols., and their annual turnover amounts to 5½ millions. The factories employ some 1500 hands, and are equipped with machinery of, from 4000 to 5000 horse-power.

The raw material used is mostly wood pulp, which is all imported. No successful arrangement has been made to make use of any locally grown product, straw, flax or other fibre. The paper turned out from the factories consists largely of wrapping paper, and printing paper of an inferior grade, no high-class paper being produced.

The import of wood pulp has increased from 19,000 tons in 1904 to 18,500 tons in 1908. In 1907 the principal sources of supply were: Germany, 10,000 tons; Brazil, 3500 tons; and Sweden, 2300 tons. Canada does not appear at all.

A large quantity of waste paper is also worked up in the local paper factories. Potato pulp is also used: in 1908 180 tons were imported from Holland and Germany.

PATENTS.

Peat fibre; Treatment of — and its manufacture into paper and board. L. Franz. Admont, Austria. Eng. Pat. 13,994, July 1, 1908.

In the mechanical preparation of peat for the manufacture of paper, the newly cut peat is charged through a hopper into a press with an endless screw, which forces it through a nozzle in the form of an endless rope, which is then cut by a revolving knife into discs of uniform thickness. These discs are broken up in water and passed through a centrifugal separator with an annular screen, through which the fine fibres pass, whilst the coarse particles are retained. The refined fibres are then treated in a washing machine to remove minute impurities and earthy matters. The washed fibre is next converted into pulp by means of a kneading machine and its particles are then separated according to size by a machine consisting of two "centrifugal plate" separators. Each grade of half-stuff thus obtained is finally mixed in beating engines with other suitable fibres for the manufacture of paper or board.—J. F. B.

Wood pulp; Process of manufacturing —. C. B. Clark, Bangor, Me. U.S. Pat. 927,950, July 13, 1909.

In the manufacture of wood pulp by the sulphite process, a portion of the liquor is removed from the digester when the digestion has proceeded so far that the resinous matters, etc., have been removed from the wood, but have not become completely resolved and soluble. The digestion is then continued with the residual liquor.—F. M.

Wood pulp mills; Reclaiming apparatus for —. C. B. Clark, Bangor, Me. U.S. Pat. 927,951, July 13, 1909.

COMBINED with the digester are two tanks, one for storing the liquor from the digester, the other for clarifying the same. The woody matter is separated from the liquor in the clarifying tank, and may be removed without disturbing the main body of the liquor.—F. M.

Hats of straw, palm-leaf, etc.; Manufacture of —. H. P. Pearson, London. U.S. Pat. 927,674, July 13, 1909.

THE process consists in treating the hat with a solution of nitrocellulose in acetone to which a "sulphurous acid" and a drying agent have been added, so that the hat receives a thin, transparent coating of the same.—F. M.

Threads and filaments of cellulose. Eng. Pats. 14,143 and 28,149. See V.

Rolls for use in printing, paper making, etc. Eng. Pat. 21,096. See V.

Impermeable leather-board. Fr. Pat. 398,199. See XIV.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Strychnine from brucine; Separation of —. G. Pinchbeck. Brit. Pharm. Conf., Newcastle, July, 1909.

THE author has found that a solution of nitrogen peroxide in nitric acid (sp. gr. 1.42) gives good results in the quantitative separation of strychnine and brucine. The amount of strychnine in *Nux vomica* and its preparations can be determined by this method. The total alkaloid from 2 grms. of the drug, 5 c.c. of the liquid extract, or 25 c.c. of the tincture, are dissolved in 15 c.c. of 3 per cent. sulphuric acid, and the temperature of the mixture brought to 25° C. 1.5 c.c. of nitric acid of sp. gr. 1.435 at 15.5° C., and containing 1 per cent. of nitrogen peroxide, are then added and the mixture set aside for 15 minutes. The liquid is made alkaline with sodium hydroxide and shaken successively with 10, 5, and 5 c.c. of chloroform. The chloroform solution is washed with sodium hydroxide solution, and distilled down to about 1 c.c. in a tared

flask. 2 c.c. of amyl alcohol are added and driven off by a current of warm air. The residue is then dried at 110° C.—F. SHDN.

Strychninesulphonic acids; Preparation of isomeric —. H. Leuchs and W. Schneider. Ber., 1909, 42, 2681—2685.

THE authors consider that there must be a $-\text{CH}_2\text{CH}_2-$ grouping in strychnine and that each of the hydrogen atoms in this grouping can be replaced by a sulphonic group to give a different sulphonic acid. Three isomeric sulphonic acids have been isolated. Strychnine is dissolved in water at 40°—50° C. by means of sulphur dioxide, and precipitated manganese dioxide is added. After the reaction the three isomeric acids can be separated by crystallisation. Strychninesulphonic acid I. has been already described (this J., 1909, 106). Strychninesulphonic acid II., $\text{C}_{21}\text{H}_{22}\text{O}_5\text{N}_2\text{S}\cdot 2\text{H}_2\text{O}$, crystallises from 300—320 parts of boiling water in short massive prisms, which dissolve easily in alcohol and alkalis, but not in dilute hydrochloric acid. It melts with decomposition at 370° C., and has $[\alpha]_D = -138^\circ$ at 20° C. in $N/10$ caustic alkali. The third isomeride can be crystallised from 10 parts of boiling water, and forms transparent flat polyhedra, or four-sided tablets. It decomposes at 276° C. (corr.). It dissolves in alkalis and in 20 per cent. hydrochloric acid, and is soluble with difficulty in alcohol. In $N/10$ sodium hydroxide, it has $[\alpha]_D = +163.3^\circ$ at 20° C. The second and third isomerides give the strychnine reaction with chromic acid.—F. SHDN.

Papaverine; Synthesis of —. A. Pictet and A. Gams. Comptes rend., 1909, 149, 210—212.

VERATROL was converted into acetoveratrone by the action of acetyl chloride and aluminium chloride. This was converted into the isonitroso derivative (m.pt. 131° C.), and reduced by stannous chloride to form the hydrochloride of aminoacetoveratrone,

On treating the salt with homoveratroyl chloride and sodium hydroxide, homoveratroylaminoacetoveratrone was produced. This has the constitution,

and forms shining leaflets melting at 142° C. On reduction with sodium amalgam in alcohol, the ketonic grouping is reduced with the production of homoveratroylhydroxy-homoveratrylamine, which forms colourless needles melting at 124° C. The elements of water were removed by the action of phosphorus pentoxide in xylene, and papaverine m.pt. 147° C. was produced.—F. SHDN.

Ergothioneine; A new base from ergot —. C. Tanret. Comptes rend., 1909, 149, 222—224.

AN alcoholic extract of ergot was treated with mercuric chloride solution, and the precipitate collected and washed. It was suspended in water, decomposed with hydrogen sulphide, and the liquid filtered and evaporated. In this way *ergothioneine hydrochloride* was obtained, 1 kilo. of ergot yielding about 1 gm. The free base,

crystallises in colourless leaflets, which melt with decomposition at 290° C. on the Maquenne block. It has $[\alpha]_D = +110^\circ$, dissolves easily in water, but only slightly in absolute alcohol. The salts with mineral acids are acid to litmus. The hydrochloride, $\text{B}\cdot\text{HCl}\cdot 2\text{H}_2\text{O}$, melts at 250° C. on the Maquenne block. Solutions of the salt give precipitates with potassium mercuric iodide, iodine in potassium iodide, and mercuric chloride, but not with picric acid or tannin.—F. SHDN.

Guaiacol and quinine as reagents for hydrogen peroxide. G. Denigès. Bull. Soc. Pharm. de Bord., June, 1909, 247; Pharm. J., July, 31, 1909.

PLACE in a test-tube, 0.3 c.c. of a 5 per cent. alcoholic solution of guaiacol, and 2 c.c. of sulphuric acid (sp. gr. 1.840), and shake; add a single drop of solution of hydrogen peroxide, and again shake. With hydrogen peroxide of about 10 volumes there is quickly developed, after the

production of a transitory brown tint, a very fine blue-green coloration. With more dilute solutions, the final blue coloration only is observed. For very dilute solutions, up to three drops may be added, shaking after each; the reaction in these conditions is still distinct with a medicinal hydrogen peroxide diluted 1:1000. The quinine reagent is applied thus:—1 to 2 centigrams of quinine sulphate is dissolved by shaking in 2 c.c. of concentrated sulphuric acid; there is then added 0.5 c.c. of hydrogen peroxide solution, with shaking, when there is quickly developed a yellow colour so intense that it may be used as a means of determining with fair accuracy the amount of hydrogen peroxide present. This reaction, though less delicate than that with guaiacol, is more characteristic, and by inversion may be used as a means of identifying quinine.

Matico leaves and oil. H. Thoms. Seventh Int. Congr. Appl. Chem., London, 1909. Z. Riech- u. Geschmackstoffe, 1909, 1, 127—128, 136—138.

AN examination was made of several varieties of matico leaves and the oil produced from them. *Piper camphoriferum* C.D.C. yielded 1.11 per cent. of oil, which had $n_D^{20} = +19^{\circ} 21'$ and the sp. gr. 0.9500 at 20°C ., and contained borneol and camphor. The oil from *Piper lineatum* Ruiz and Pavon amounts to about 0.44 per cent., and has $n_D^{20} = +8^{\circ} 45'$ and the sp. gr. 0.958. It distils for the most part between 140° and 150°C . at 15 mm., and appears to contain a fair proportion of a sesquiterpene. *Piper augustifolium* var. *Ossanum* C.D.C. contains 0.87 per cent. of oil, in which Japan camphor and borneol are present. The oil from *Piper acutifolium* R. and P. var. *suberbasifolium* was found to contain small amounts of acids and phenols, together with pinene, dillapiol, and a sesquiterpene.—F. SHDN.

Sapphire: Presence of dimethoxy-2,3-methylenedioxy-4,5-allyl-1-benzene in the essential oil of —. M. Delépine. Comptes rend., 1909, 149, 215—217. (See this J., 1909, 623.)

ON distilling that portion of the essential oil of sapphire (*Crithmum maritimum* L. Omb.) which boils below 200°C ., the author obtained two fractions. About 5 per cent. of the total amount of oil boiled between 90° and 95°C . at 13 mm., and about 40 per cent. at 157° — 158°C . at 13 mm. The second fraction consists of a substance, $\text{C}_{15}\text{H}_{14}\text{O}_4$, isomeric with apiol, and found to be identical with dimethoxy-2,3-methylenedioxy-4,5-allyl-1-benzene, the dillapiol of Thoms (Arch. Pharm., 1904, 242, 344). One kilo. of the fresh seeds of sapphire yield 7—8 grms. of oil, whilst the dried seeds yield 30 grms.—F. SHDN.

Philippine terpenes and essential oils. Manila elemi. R. F. Bacon. Philippine J. of Sci., A, 1909, 4, 93—111.

THE source of true Manila elemi is *Canarium luzonicum* A. Gray. The greater proportion of different samples of elemi yielded phellandrene on distillation; whilst a few were found to contain limonene. 12—18 per cent. of elemi consists of terpenes, 12—15 per cent. is a higher boiling oil, from which Semmler has isolated elemicin, whilst the remainder, about 70 per cent., is a light brown, transparent resin, with a brilliant fracture. The resin dissolves in most solvents and the solutions on evaporating leave a brilliant varnish, which, however, dries slowly. Mixed with copal it gives more satisfactory results. Limonene hydrochloride was treated with magnesium, and the product allowed to act upon orthoformic ester. In this way, dihydroterpene, and probably, diterpene were produced. When the magnesium compound of limonene hydrobromide was treated with benzaldehyde, dihydrolimonene was obtained. Similar results were obtained when acetaldehyde was used in place of benzaldehyde. A mixture of limonene dihydrobromide and benzaldehyde was allowed to act upon magnesium, when a white crystalline compound was obtained which decomposes at about 212°C ., and has the composition $\text{C}_{10}\text{H}_{16}\text{Br}_2$ or $\text{C}_{20}\text{H}_{32}\text{Br}_4$. Tetrahydrolimonene was also produced. α -Phellandrene hydrobromide subjected to the Grignard reaction in the presence of benzaldehyde, gave benzoin. α -Phellandrene

hydrochloride can be converted into dipentene by the action of an alcoholic solution of potassium hydroxide.—F. SHDN.

Philippine terpenes and essential oils. Lemon grass oil. Blumea balsamifera. Lantana camara. Oil of Ylang-ylang. R. F. Bacon. Philippine J. Sci., A, 1909, 4, 111—132.

THE plant, *Andropogon citratus* D.C., from which lemon grass oil is obtained, is found in the wild state and is cultivated in the Philippines. With good ground and three cuttings of the grass per year, a yield of about 240—300 kilos. of oil per hectare can be obtained. Lemon grass is not profitable as a permanent crop. Several quantities of the grass grown by the author yielded oil containing 77—79 per cent. of citral, and of good quality.

The leaves of *Blumea balsamifera* D.C. contain 0.1 to 0.4 per cent. of a yellow oil, which consists of nearly pure l-borneol. This would work out to a yield of 50—200 kilos. of oil per hectare.

An oil, with an odour like that of sage and boiling below 140°C . at 11 mm. was obtained from the leaves of *Lantana camara* L., which is a very abundant weed.

AFTER further work with various samples of Ylang-ylang oil, the author considers that it is characterised by a low refractive index, low optical activity, and high ester numbers. A quantity of the flowers was extracted with light petroleum, and the solvent distilled off below 40°C . at 40 mm. A dark resinous oil was obtained, which gives the true odour of the flowers when diluted. It had the sp. gr. 0.940 at $30^{\circ}/4^{\circ} \text{C}$., $n_D^{30} = 1.4920$ at 30°C ., ester value 135, and acetyl value 208.

THE leaves of a species of *Fagara* yield an oil containing limonene. The oil from the mint, *Hyptis suaveolens* Poir., contains menthol. *Champaca* flowers from *Michelia champaca* and *M. longifolia* Bl. were subjected to enflourage with paraffin oil. By this means the paraffin acquired a fine strong odour, and might be used as a base for perfumes. The flowers of *Plumeria acutifolia* Poir., the supposed source of "frangipani," were extracted with light petroleum, and gave a gummy oil with a satisfactory odour. Oil of zedoary (*Curcuma zedoaria* Rose.) has a dark greenish-brown colour, with the sp. gr. 0.933 at $30^{\circ}/4^{\circ} \text{C}$., and $n_D^{30} = 1.4920$ at 30°C . The oil dissolves in two volumes of 80 per cent. alcohol.—F. SHDN.

Philippine terpenes and essential oils. Balao resin. R. F. Bacon. Philip. J. Sci., A, 1909, 4, 121—127.

THE source of Balao resin is *Dipterocarpus vernicifluus* Blanco, or *D. grandiflorus* Blanco. It is used by the Philippine natives as a varnish, and although it gives a tough hard coat, dries very slowly. A quantity of the resin was distilled at ordinary pressure, and the volatile portion redistilled in a vacuum. In this way a sesquiterpene was separated, which boiled at 118° — 119°C . at 8 mm., had the sp. gr. 0.9104 at $30^{\circ}/4^{\circ} \text{C}$., $n_D^{30} = 1.4956$ at 30°C ., and $n_D^{30} = +116.4$ at 30°C . It boils at 261° — 262.4° (corr.) at ordinary pressure, when it becomes slightly yellow. The oil of *supa* contains a large amount of eadinene.—F. SHDN.

Camphor: Determination of — in spirit of camphor. E. Deussen. Archiv. Pharm., 1909, 247, 307—313.

FIVE grms. of the spirit of camphor are weighed off into a tared 50 c.c. Erlenmeyer flask, then treated with exactly 20 grms. of cold-saturated ammonium sulphate solution and 30 grms. of water. The mixture is well shaken, and set aside in an ice-chamber for about 12 hours. The separated camphor is collected on a small smooth filter, and washed with 70 to 90 grms. of water until free from sulphate. The moist magma of camphor is drained and aggregated into a ball with a nickel spatula. The filter is covered with a watch-glass, and another small watch-glass and a piece of card, about the size of a postcard, are tared. The camphor is spread out thinly with the nickel spatula upon a porous tile, covered for some minutes with a watch-glass, then transferred quantitatively to the tared card, covered with the tared watch-glass, and weighed. The amount of camphor found by this process is within 4 to 6 per cent. of the total quantity present.

Natural (dextro) camphor thus obtained has a marked extro-rotation in alcohol or benzene solution, and the amphoteric acid it yields on oxidation with nitric acid, melts at 187° C. Artificial camphor, *i*- (or racemic) camphor, obtained under like conditions, is optically inactive, and the camphoric acid it affords on oxidation melts at 204°–205° C.—J. O. B.

Organic arsenic compounds. Internat. Congr. of Appl. Chem., 1909. W. Harrison Martindale.

THE author has prepared a number of organic arsenic compounds, which appeared likely to prove of therapeutic interest. Many of these bodies he made on a manufacturing or experimental scale, and in most instances provided methods of procedure and has pointed out means of overcoming difficulties encountered. Amongst other data the melting points of the substances, when of value, the arsenic contents according to theory and as found practically, the solubilities, and the relative toxicities have received attention.

A few definitions will now be useful.

Arsenic acid indicates arsenic acid, $\text{AsO}_3(\text{OH})_2$, in which one of the hydroxyls is replaced by an organic radiide.

Arsinic acid constitutes a dialkyl or dialkyl derivative of arsenic acid—i.e., cacodylic acid—and its homologues; e.g., phenyl-arsinic acid, $(\text{C}_6\text{H}_5)_2\text{AsO}_3\text{H}$. It should be understood that the French and German chemists do not as a rule make these distinctions.

Arylarsonate.—This term is used to indicate an aromatic arsonate.

Arsanilic acid is a name given to *p*-aminophenyl arsonic acid, the sodium salt of which is in such repute, therapeutically, at the present day.

Arsenic.—This term one finds in the French literature as referring to aromatic arsenic bodies containing two atoms of arsenic believed to be coupled together by a double linkage—e.g., $\text{C}_6\text{H}_5-\text{As}=\text{As}-\text{C}_6\text{H}_5$, arsenobenzene, comparable with $\text{C}_6\text{H}_5-\text{N}=\text{N}-\text{C}_6\text{H}_5$, azobenzene.

(i.) **Aliphatic series.**—The Cacodyle bodies (of the aliphatic series) are now superseded by substances better from the therapeutic point of view.

Cacodylic acid, or dimethyl-arsinic acid, $(\text{CH}_3)_2\text{AsO}_3\text{H}$. Cacodylic acid is prepared by the oxidation of arsenium dimethyl (cacodyle), $(\text{CH}_3)_2\text{As}-\text{As}(\text{CH}_3)_2$, as it is more correct to view cacodyle as tetramethyldiarsine and all cacodylates as derived from this diarsine, and of cacodyl oxide, $(\text{CH}_3)_4\text{As}_2\text{O}$.

A portion of Cadet's liquid is surrounded by cold water in a suitable vessel, and mercuric oxide is added in small quantities at a time. The vigorous reaction is further controlled by adding water:

If the mercuric oxide be in excess, part of the acid forms mercury cacodylate. When the odour of cacodyle has disappeared one adds, drop by drop, cacodyl oxide to reduce the mercury cacodylate. This point is known by the odour becoming perceptible, and by the fact that the solution no longer deposits metal mercury. The liquor is evaporated to dryness and the acid recrystallised from boiling alcohol.

Cacodylic acid is neutral to methyl orange and phenolphthalein. It melts at 200° C., and has an arsenic content of 54.3 per cent.; solubility, 2 in 1 of water (about) and 1 in 4 of 90 per cent. alcohol. Cacodyle is poisonous, but the acid and its salts are comparatively harmless. The latter have, however, fallen into disfavour by reason of this harmlessness—i.e., their stability and lack of arsenical effect. They pass through the system and appear, principally in the urine, in an unaltered condition. Another portion is reduced in passage through the organism to a volatile cacodyl oxide which is exhaled.¹ The salts of cacodylic acid used in medicine may be briefly enumerated:

Sodium cacodylate (P. Helv.), $(\text{CH}_3)_2\text{AsO}_2\text{Na} + 3\text{H}_2\text{O}$. Arsenic-content, 35 per cent. Commercially, usually contains 18 to 25 per cent. of water. Soluble 2 in 1 water.

Magnesium cacodylate, $[(\text{CH}_3)_2\text{AsO}_2]_2\text{Mg} \cdot \text{H}_2\text{O}$. White amorphous powder, soluble 1 in 3.

Iron cacodylate, $[(\text{CH}_3)_2\text{AsO}_2]_3\text{Fe}$. Yellowish powder, soluble 1 in 15 in water.

Guaiacol cacodylate, $(\text{CH}_3)_2\text{AsO} \cdot \text{O} \cdot \text{C}_6\text{H}_4(\text{OCH}_3)(?)$. Valeur states the composition of this substance is apparently simply $(\text{CH}_3)_2\text{AsO} \cdot \text{OH} \cdot \text{C}_6\text{H}_4\text{OH}(\text{OCH}_3)$ —i.e., equimolecular proportions of each.²

Strychnine cacodylate, $\text{C}_{21}\text{H}_{22}\text{N}_2\text{O}_2 \cdot (\text{CH}_3)_2\text{AsO} \cdot \text{OH}$. White crystalline powder.

Ethyl cacodylic (Diethylarsinic) acid, $(\text{C}_2\text{H}_5)_2\text{AsO}_3\text{H}$, and the propyl derivative $(\text{C}_3\text{H}_7)_2\text{AsO}_3\text{H}$ have also been prepared.

Di-sodium methylarsenate, or, sodium mono-methyl arsonate, arrhenal. "New Cacodyle," $\text{CH}_3\text{AsO}(\text{ONa})_2$. Prepared by the interaction of methyl iodide and sodium arsenate in presence of excess of alkali. Soluble about 1 in 1 in water, only slightly in alcohol 90 per cent. A solution of the salt (strongly acidified) with hydrogen sulphide gives a precipitate of mono- and di-sulphide of methylarsine. Arrhenal solutions do not precipitate with baryta water (sodium cacodylate does), nor with magnesia mixture (nor does sodium cacodylate), nor by cold solution of calcium chloride (ditto sodium cacodylate), but are precipitated by nitrates of silver (white silky ppt.; sodium cacodylate none) and mercury (also sodium cacodylate; both yellow, arrhenal the darker of the two). Mercuric chloride, gives a reddish-yellow ppt. with arrhenal, and a white precipitate with sodium cacodylate. Sodium-*p*-aminophenylarsonate gives a white precipitate with these reagents in every case. Arrhenal may be estimated by dissolving about 0.2 gm. in 1 to 2 c.c. of water and adding 15 to 20 c.c. of hydrochloric and hypophosphorous acid mixture.³ After twelve hours dilute with 15 to 20 c.c. of water and filter, washing the residue with water. To the filter and its contents add a known excess of N/10 iodine solution, shake well, and titrate excess with sodium thiosulphate—

The black body CH_3As is quantitatively produced from 1 molecule $\text{CH}_3\text{AsO}(\text{ONa})_2$ therefore 4 atoms of iodine = 1 molecule arrhenal. Bougault⁴ suggested this reagent for testing for traces of arsenic in glycerin (arsenite or arsenate) and for cacodylate. For the latter it is exceedingly delicate.

To prepare the test, dissolve 20 grms. sodium hypophosphite in 20 c.c. water and add 200 c.c. hydrochloric acid (1.17 sp. gr.). Sodium chloride is thrown out and removed. To apply the test, 5 c.c. glycerin is mixed with 10 c.c. of the reagent. Place in water-bath—brown deposit.

This methylarsine,⁵ CH_3As , is also obtainable by action of sodium hypophosphite, and sulphuric acid on sodium cacodylate. $2\text{H}_3\text{PO}_2 + \text{AsCH}_3\text{O}(\text{OH})_2 = 2\text{H}_3\text{PO}_3 + \text{CH}_3\text{As} + \text{H}_2\text{O}$, as a yellow oil insoluble in water, with strong garlic odour. It polymerises to $(\text{CH}_3\text{As})_n$ —probably the same body as made by Bougault by reducing methyl arsonic acid. (Arrhenal has also been standardised by precipitating methylarsenate of silver with aid of excess of AgNO_3 and estimating the excess of latter with thiocyanate, using iron alum as indicator). Arrhenal is reduced by sulphur dioxide to methylarsenoxide, AsCH_3O . The di-sodium derivative of this, $\text{AsCH}_3\text{O}(\text{ONa})_2$, yields with methyl iodide cacodylic acid, which on reduction gives cacodyl oxide, $(\text{CH}_3)_4\text{As}_2\text{O}$, the sodium compound of which, $\text{As}(\text{CH}_3)_2\text{ONa}$, reacts with methyl iodide to form trimethylarsine, $\text{As}(\text{CH}_3)_3$ —two arsenious compounds can be made containing one, two, or three methyl groups.⁶

Di-iodomethylarsonic acid,⁷ $\text{CHI}_2\text{AsO}(\text{OH})_2 \cdot \text{H}_2\text{O}$. May be prepared by oxidising with nitric acid in the cold the body CHI_2AsI_2 , a constituent of the dense black oil formed by interaction of 5 parts amorphous arsenic with 42 parts iodoform in presence of benzene or toluene at water bath temperature, otherwise the reaction may be explosive. When the interaction is complete, distil off the solvent. After oxidising, filter off the magma (much charged with iodine), wash it with cold water, and

evaporate the acid liquor gently at not exceeding 40°–50°. Yellow crystals throw out containing H_2O , which should be recrystallised from warm water. The insoluble portion is treated with boiling benzene or toluene to remove the iodine. The residual yellow powder contains tetraiodocacodylic acid, which one purifies by dissolving in ammonia and reprecipitating with acid. For oxidising I used strong nitric acid added to the substance with the layer of supernatant toluene.

The following formulae convey an idea of the interactions:

Sodium di-iodo-methyl-arsenate. $\text{CHI}_2\text{AsO.OH.ONa} + \text{Aq.}$ This salt I prepared in feathery crystals in appearance similar to quinine sulphate. The acid was dissolved in alcohol and neutralised with sodium bicarbonate, adding water to aid solution. It is very soluble in water.

Tetra-iodocacodylic acid. $\text{As}(\text{CHI}_2)_2\text{O.OH}$. This acid forms small yellow crystals insoluble in water.

Sodium tetra-iodocacodylate. $(\text{CHI}_2)_2\text{AsO.ONa.6H}_2\text{O}$. This salt was obtained in beautiful yellowish crystals from the above acid by means of a water-alcohol solution.

Amorphous arsenic, referred to previously, is very active chemically. It, for example, unites at ordinary temperature with methyl iodide, whereas ordinary powdered arsenic has to be heated to 160°–200° to react with this substance. Similarly chloroform decomposes:

This amorphous form of arsenic is made by precipitating a hydrochloric acid solution of arsenious acid with stannous chloride or a hypophosphite. I found it was best to work in concentrated arsenical solution, adding the hypophosphite in the solid condition in portions and heating the while. I have not employed stannous chloride for the purpose. Assumed reaction:

Tetra-methyl arsonium iodide. $\text{As}(\text{CH}_3)_4\text{I}$.⁸ A white substance, becoming reddish brown in the light, made by heating arsenic with CH_3I at 220° for twenty-four hours. Crystallisable from methyl alcohol in tetrahedra. The substance yields coloured precipitates with many metallic salts. Author's experiments with it were not successful. He tried the amorphous arsenic in addition to the ordinary form. Special apparatus is necessary to overcome the difficulties usually appertaining to sealed tubes, stoppered pressure bottles, etc.

Acetic arsenious anhydride,⁹ or triacetic arsenious anhydride. $\text{As}(\text{O.CH}_2\text{CO})_3$. Is prepared by dissolving arsenious acid in acetic anhydride, and is obtainable as colourless needles melting at 82°. Readily soluble in chloroform and ethyl acetate, less in benzene and carbon disulphide. Decomposes in moist air. It is difficult to obtain in the anhydride form. A molecular proportion of arsenious oxide readily dissolves in six molecular proportions of acetic anhydride. The arsenic content of two fractions removed from the crystallising dish indicated dissolution.

Magnesium methylarsenate. $\text{C}_2\text{H}_5\text{AsO.OOMg}$. Is prepared¹⁰ by treating a solution of potassium arsenite with ethyl iodide. When the reaction is complete the solution is acidified with dilute hydrochloric acid and filtered. Chlorine is passed into the filtrate, and the iodine precipitated is removed by filtration. The liquid is made alkaline with ammonia, treated with a large excess of magnesia mixture, and left twenty-four hours. The liquid is filtered and evaporated. The salt is readily soluble in acids, but not in alkalies—very slightly in water. Usually contains 1 molecule of water. It is decomposed by heat into magnesium oxide, metallic arsenic, methane, ethylene, and water.

It is a little difficult to understand why, according to these conditions, an ethyl-arsenite of potash is not produced with formula

and ultimately the magnesium body of the formula

as the result of passing chlorine into the liquor, as above mentioned. Apparently there is a change over to the pentavalent arsenic thus

without the actual assumption of fresh oxygen. There is proof of the fact that the alkyl radicle is directly joined to the arsenic by the reduction to the corresponding arsine which contains the radicle in direct union with arsenic:

*Normal propyl arsonic acid.*¹¹ $\text{C}_3\text{H}_7\text{AsO}(\text{OH})_2$. To arsenious oxide (1 mol. proportion) and potassium hydroxide (6 mol. weights) water *q.s.* is added to dissolve. After cooling add alcohol *q.s.* to incipient precipitation, then 2 mol. proportions *n*-propyl iodide and shake. Either some propyl iodide or some potassium arsenite will be precipitated, but the mixture is made homogeneous by adding either water or alcohol, or both. Keep in a tight stoppered bottle for a number of days. $\text{As}(\text{OK})_3$ is first formed, leading to production of $(\text{C}_3\text{H}_7)_2\text{AsO}(\text{OK})_2$ and KI , and the unavoidable side reaction:—

also takes place. Distil to remove alcohol and the ethyl propyl ether. Add hydrochloric acid to incipient precipitation, then pass chlorine into the liquid until the pure white double salt $\text{As}_2\text{O}_3.2\text{KI}$ first formed is dissolved and all the iodine precipitated. The filtrate is then heated with magnesia mixture to precipitate the arsenate; on boiling the filtrate from the ammonium magnesium arsenate with more magnesia mixture, the magnesium salt of normal propyl arsonic acid precipitates as pearly white soapy crystals. The yield is stated to be 42 per cent. The salt has the composition $\text{C}_3\text{H}_7\text{AsO.OOMg}$. It contains, like magnesium ammonium arsenate dried over 100°, 1 mol. of water to 2 of the anhydrous salt. The free acid (*n*-propyl arsonic), in acicular crystals, is made by treating the magnesium body in the cold with a calculated quantity of concentrated sulphuric acid and extracting with alcohol. The same remarks regarding the possible formation of potassium propyl arsenite, etc., apply as under "Magnesium Ethyl Arsonate."

Iso-amyl arsonic acid. $\text{C}_5\text{H}_{11}\text{AsO}(\text{OH})_2$. The preparation of this acid is analogous with that for normal propyl arsonic acid by treatment of arsenious acid 150 parts (2 mols.) with potassium hydroxide 254 parts (6 mols.) and iso-amyl iodide 300 parts (2 mols.) in presence of alcohol. After two to three days distil off the alcohol, carefully neutralise the liquid, and filter from the double salt $\text{As}_2\text{O}_3.2\text{KI}$. Upon acidifying after some time shining crystals form of the composition $\text{C}_5\text{H}_{11}\text{AsO}(\text{OH})_2$.

The same remarks apply here as under the corresponding ethyl and propyl bodies.

Up to the present only a few of the arsonic acids in the aliphatic series have been prepared and examined; obviously of each acid innumerable salts suggest themselves as worthy of experimental trial. In the aromatic series, however, experimentation has been more prolific.

(ii.) *Aromatic series. Potassium phenyl-arsenite.* $\text{C}_6\text{H}_5\text{As}(\text{OK})_2$. Arsenious chloride and mercury diphenyl combine¹² by heating one hour at water-bath temperature

¹² Berichte, 8, 1316, 9, 1566.

with a reflux condenser, forming phenyl-arsenious chloride and corrosive sublimate:—

The organic body is separated from the arsenious trichloride employed in excess, by fractionating (boiling-point 252° — 255° C.). It is very caustic to the skin—this I most certainly verified. Another way of making is to heat triphenylarsine with arsenic trichloride.¹³ Phenyl arsenious chloride is not affected by water, but can be converted by alcoholic potash into potassium phenyl-arsenite, potassium chloride separating out. Though at first obtained in yellow (impure) crystals it was ultimately purified to white from absolute alcohol. It is a very poisonous substance. Soluble in absolute alcohol in all proportions.

Sodium phenyl-arsenite. $\text{C}_6\text{H}_5\text{As}(\text{ONa})_2$. Also produced from the acid by neutralising.

Note.—The necessary diphenyl mercury for the above-mentioned method of manufacture is prepared by mixing benzene monobromide with an equal volume of xylene and excess of sodium amalgam containing not too much sodium.

A little acetic ether is a useful addition. The reaction—

—is complete after a few hours' boiling. A little benzene is added to the flask containing the diphenyl body, sodium bromide and metal mercury, the liquor is filtered off in a hot-water funnel, and the substance recrystallised from benzol. Melting-point, 120° . It may be pointed out this method is equally applicable for producing the dihalogen derivative of a primary arsine in the fatty series,¹⁴ e.g.:

Potassium phenyl arsenite on warming with concentrated hydrochloric acid is converted into phenyl-arsen-chloride again. By using hydrobromic or hydriodic acid phenyl-arsen bromide or iodide can be made.

Sodium in absolute alcohol or sodium amalgam reduces phenyl arsenious chloride to arsenobenzene¹⁵—

but hydrogen peroxide will oxidise it to—

Phenyl-arsonic acid. $\text{C}_6\text{H}_5\text{AsO}(\text{OH})_2$. On saturating phenyl arsenious chloride with chlorine, *phenyl-arsenic tetrachloride*, $\text{C}_6\text{H}_5\text{AsCl}_4$, is formed—a yellow solid substance. This decomposes violently with water or moist air, forming a solid oxychloride, $\text{C}_6\text{H}_5\text{AsOCl}_2$,¹⁶ at first (probably). On further addition of water the dibasic phenyl-arsonic acid as above is produced, forming long white needles soluble in cold water to some extent, very soluble in hot. Melting point 168° .

In author's experiments, a few drops of water added, rendered the chlorination more vigorous. A shorter method of manufacture is to pass chlorine into a mixture of 25 parts phenyl-arsenious chloride, $\text{C}_6\text{H}_5\text{AsCl}_2$, with 100 parts of water until the oily globules have disappeared. One then warms to the point at which on cooling the liquid remains clear, evaporates to dryness to derive off hydrochloric acid, and then purifies by recrystallisation from warm water.¹⁷

Diphenyl-arsinic acid. (Phenyl-cacodylic acid) $(\text{C}_6\text{H}_5)_2\text{AsO} \cdot \text{OH}$. To produce this acid one may start from diphenylarsenous chloride, $(\text{C}_6\text{H}_5)_2\text{AsCl}$. This body is left behind as a much less volatile fraction (333°) on fractionating mono-phenyl-arsenious chloride from the arsenious trichloride as previously described. The best method of procedure is to pass chlorine rapidly through diphenyl-arsenous chloride, $(\text{C}_6\text{H}_5)_2\text{AsCl}$, in the presence of a considerable amount of water, then warm to 60° — 70° , not exceeding this temperature. When chlorination is completed with formation of the trichloride $(\text{C}_6\text{H}_5)_2\text{AsCl}_3$, evaporate on a water-bath to dryness, and take up the residue with hot water, from which the acid separates.¹⁸

In author's experiments ether was used as solvent; otherwise the whole mass was likely to go solid.

Diphenyl-arsinic acid is obtainable in long needles.

Soluble with difficulty in cold water, easily in hot. Melting at 174° .

Another way of making phenyl-cacodylic acid would be by oxidising diphenyl-arsen oxide, $(\text{C}_6\text{H}_5)_4\text{As}_2\text{O}$ (phenyl-cacodyl oxide), produced by the action of magnesium phenylbromide on arsenious acid in ethereal solution.¹⁹ Approximately the reaction may be represented by the following equation:

The magnesium in finely powdered condition is dissolved in the benzene monobromide in absolute ether, and the arsenious oxide is added; it dissolves with heat evolution. After a little time the brown magnesium body separates in an apparently crystalline condition. The mixture is heated on the water-bath half an hour (diphenyl body is formed in this period and triphenyl arsine after three hours' heating). Distil off part of the ether, then add carefully water and acetic acid. The ether layer is removed, dried with sodium sulphate, filtered, and evaporated: an oily body is obtained which becomes solid in a few days. It is dried on porous clay and then has melting-point 90° — 91° . The precaution specially necessary in this reaction, is to dehydrate the ether with sodium and to use a little methyl or ethyl iodide to promote interaction. The compound is to be recrystallised from ether.

The author oxidised this diphenyl arsenious oxide with hydrogen peroxide.

(There was more reaction in the presence of alkali.) Ultimately effervescence ceased and the substance (sodium phenyl-cacodylate) became practically solid.

Although Bansen originally stated that cacodylic acid was non-poisonous, it was proved later by Schulz²⁰ that 0.3 grm. of (pure) acid neutralised with alkali was a fatal dose for a rabbit. Schulz advanced the following as the possible explanation of what occurs in the body:

(a) Mono-acid—

(b) Di-acid—

The formation of benzene seems improbable. In any case both the phenyl-arsonic and diphenyl-arsinic acids are poisonous.

*Phenyl-arsenious oxide.*²¹ $\text{C}_6\text{H}_5\text{AsO}$. This body (mentioned for theoretical interest only) is prepared on lines exactly analogous with the Baeyer method of making cacodyl oxide from cacodyl chloride by pouring water on to phenyl-arsenious chloride, warming gently, and adding sodium carbonate in small portions until effervescence ceases. Cool, and pour the aqueous liquid from the cake, dissolve the latter in hot alcohol, filter, and evaporate over sulphuric acid. The oxide is obtained as a crystalline crust. At ordinary temperatures it has the odour of anise; heated it is most penetrating to the nostrils. Another way of proceeding²² is to act on dichlorophenyl-arsine with caustic or carbonated soda—

Phenyl-arsenious oxide is insoluble in water. It melts at 119° — 120° . Warmed with hydrochloric acid, phenyl-arsenous chloride is again produced—

Benzyl-arsonic acid.—This body is stated to be easily prepared according to the following reaction:

Dissolve the substances in alcohol and water as under iso-amylarsonic acid, free from alcohol by distillation; first neutralise, then carefully acidify the residue with hydrochloric acid. A precipitation of benzyl-arsonic acid

to the extent of 60 per cent. is stated to occur. The acid has melting-point 167°. Soluble with difficulty in cold water, but easily in hot.

p-Tolyl-arsenic acid, $\text{CH}_3\text{C}_6\text{H}_4\cdot\text{AsO}(\text{OH})_2$, is of interest in view of a recent report of its efficacy on trypanosomes (*vide* Sodium Arsanilate).

In making this acid chlorine was rapidly passed through *p*-tolyl-arsenious chloride, $\text{C}_7\text{H}_7\text{AsCl}_2$, in a vessel with five times its weight of water, then warmed to 60°–70°. When chlorination was complete the liquor was evaporated on a water-bath to dryness. The residue was taken up with hot water, from which the acid crystallises.

Tolyl arsenious chloride is made from arsenic trichloride and mercury ditolyl, $\text{Hg}(\text{C}_7\text{H}_7)_2$. The ditolyl body is made from *p*-tolyl bromide, which in turn is prepared by the action of bromine in the cold on toluene.

p-Benzo-arsenic acid, $\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{AsO}(\text{OH})_2$. This acid has been prepared by oxidising *p*-tolyl-arsenic acid with alkaline permanganate.

p-Hydroxyphenyl-arsenic acid $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{AsO}(\text{OH})_2$, two forms of hydroxytolyl-arsenic acid

phenyl-glycine *p*-arsenic acid

sulphur derivatives *p*-amino-phenyl-arsenious sulphide $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{AsS}$, *p*-acetyl-amino-phenyl-arsenic sesquisulphide $\text{O}(\text{NH}\cdot\text{As}\cdot\text{C}_6\text{H}_4\cdot\text{As})_2\text{S}_3$, and phenyl-glycine arsenic disulphide $\text{COOH}\cdot\text{CH}_2\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{AsS}_2$ have been made the subjects of German patents.²³

Sodium *p*-aminophenyl arsanilate, or arsamin, atoxyl, soamin, sodium arsanilate, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{AsO}\cdot\text{OH}\cdot\text{ONa} + \text{Aq}$. For method of manufacture of this body Ehrlich and Berthelm²⁴ should be consulted.

This salt is stated to crystallise with 5H₂O and to lose 3H₂O by efflorescence. Its arsenic content varies in consequence from about 20 to 25 per cent. The amount of water found by Moore, Nierenstein, and Todd²⁵ was rather less than 4H₂O. Author's experiments indicated practically 4½H₂O in a foreign commercial product, while his own substance contained 19 to 22 per cent.

Ehrlich and Berthelm state that the salt is produced with 2 and with 6 H₂O, according to the solvent employed. Author assumes the tendency to efflorescence to be due to the fact that the salt has been crystallised from water. To employ alcohol would therefore be very much better.

The anhydrous substance is readily soluble in methyl alcohol, and practically insoluble in ether, acetone, benzol, or chloroform. Reactions of its aqueous solution with solutions of various metallic salts and a detailed account of its therapeutic action are given.²⁶ That atoxyl is sodium arsanilate, and not the anilide of arsenic acid, $\text{C}_6\text{H}_5\text{NH}\cdot(\text{OH})_2\text{AsO}$, nor the anilide of met-arsenic acid, $\text{C}_6\text{H}_5\text{NH}\cdot\text{AsO}_2$, can be shown—(1) By the fact that it cannot be hydrolysed into aniline; (2) it contains a primary amino group; (3) the arsenic-acid radicle can be replaced by iodine yielding *p*-iodoaniline. The now somewhat classic confusion between Béchamp's arsenic anilide and the acid obtained from commercial atoxyl, which was called meta-arsenic anilide (though a sodium salt), may be cleared up by the statement that Ehrlich and Berthelm found the two substances to be identical chemically.

Arsanilic acid, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{AsO}(\text{OH})_2$, is slightly basic. Its hydrochloride is immediately hydrolysed by water. It is soluble, however, in methyl and ethyl alcohol.

The sulphate has the composition

Acetyl *p*-aminophenyl-arsenic acid,

forms glistening leaflets, easily hydrolysed by hot alkalis and acids, does not react with naphthoquinone sulphonie acid, and forms a sodium salt. To show basicity of the substance arsanilic acid, if one adds mineral acid in excess to a solution of atoxyl, the precipitate first formed redissolves;

acetic acid in excess, however, does not cause re-solution, for which reason sodium acetate throws out *p*-aminophenyl-arsenic acid from a solution in mineral acid. These facts may well be tabulated:

(1) Sodium arsanilate + H₂SO₄ = arsanilic acid → H₂SO₄ salt.

(2) Sodium arsanilate + acetic acid = arsanilic acid → not acetic acid salt.

(3) [Arsanilic acid]·H₂SO₄ + sodium acetate = [arsanilic acid + acetic acid] + Na₂SO₄.

Atoxyl solutions should be made with cold boiled water, unsterilised and stored in the dark.²⁷ Before use boil two minutes. Must not be allowed to become alkaline. Boiling the solution is stated to be liable to liberate arsenic acid.

Gadamar says²⁸ that atoxyl is not decomposed by hydrogen-sulphide solution. This is believed to be true to a limited degree only,²⁹ according to the temperature employed—i.e., if the hydrochloric solution be hot the arsenic is precipitated quantitatively, whereas at 0° C. the precipitate is probably $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{AsS}_2$. I understand, nevertheless, that Lockermann is in error, and that the anilin radicle is present in his arsenic precipitate.

Atoxyl may, it is stated, be estimated in manner exactly as for Arrhenal (*q.v.*), 4 atoms of iodine corresponding to 1 molecule of atoxyl.³⁰ In trying the method I found that the substance turned yellow as distinct from the arrhenal result, and the wash-liquor caused further deposition. I discarded this method in favour of fusing with magnesium nitrate and the volumetric process described later.

Detection in urine.—If 5 c.c. of normal urine is heated to 100° for thirty to forty-five minutes with 10 c.c. of the hydrochloric-hypophosphorous acid reagent and a drop of N/10 iodine solution, it assumes a dark-brown colour, while if 0.25 mgrm. of atoxyl or arrhenal be present the darkening is only slight. 0.01 grm. of atoxyl per 250 c.c. of urine may be detected by this reagent.³⁰ Further, delicate tests for atoxyl are supplied by Covelli.³¹

Sodium acetyl-*p*-amino-phenylarsenate.

Also arsacetin (reg. trade mark; patented), acetyl-atoxyl. This salt is prepared³² by neutralising acetyl-arsanilic acid with warm concentrated soda solution *q.v.* It occurs as a white crystalline powder soluble 1 in 10 of water.

For acetylating sodium arsanilate 31 parts are treated with acetic anhydride 55, adding, after interaction, water 300 and hydrochloric acid 52 parts.

This body is stated to be even less toxic than atoxyl. Solutions of acetyl-atoxyl can be sterilised by heat without decomposition, and can be stored without alteration. Sodium benzoyl-arsanilate, $\text{NH}\cdot\text{OC}\cdot\text{C}_6\text{H}_5\cdot\text{C}_6\text{H}_4\cdot\text{AsO}\cdot\text{OH}\cdot\text{ONa}$,

Sodium benzoyl-acetyl-arsanilate,

as also

Sodium-*p*-hydroxy-phenyl-arsenate, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{AsO}\cdot\text{OH}\cdot\text{ONa}$ have been prepared. These bodies have been tested³³ both as to protein precipitation and action on trypanosomes: those yielding precipitates with protein containing arsenic were the most active on trypanosomes. The hydroxyl body last mentioned and the benzoyl-acetyl-atoxyl were void of action. The conclusion arrived at was that the NH₂ grouping is an essential adjuvant to the arsenic in combating trypanosomes.

Dimethyl amino-phenyl-arsenic acid,

p-dimethylaminophenyl arsenic acid³⁴ (previously described by Michaelis and V. Brnder, "Ann." 320, 296)

is made by oxidising dimethyl-anilin-arsenious oxide, $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{AsO}$, with hydrogen peroxide in presence of alkali. Pour over 5 grms. of the body in question 100 c.c. water and 20 c.c. of 15 per cent. NaOH and then gradually 6 c.c. of 30 per cent. H_2O_2 and precipitate as soon as complete solution occurs with dilute acetic acid. Instead of isolating this dimethyl-aniline-arsenious oxide (see "Ann." 270, 139, for preparation) one can convert it direct: 15 grms. dimethyl-aniline are mixed with 25 grms. arsenious chloride and heated two hours on a water-bath, and poured into 300 to 400 c.c. cold water. The mixture dissolves in the water. Add sodium hydroxide in excess until the dimethyl-anilin-arsenious oxide at first thrown out redissolves (it goes milky at first). Shake out the dimethylanilin used in excess with petroleum ether and add hydrogen peroxide to the alkaline liquor. Dilute acetic acid separates the body. (To ascertain whether sufficient hydrogen peroxide had been used a little *liquor iodi* was employed, causing chocolate precipitate showing excess of hydrogen peroxide).

then

Sodium dimethylaminophenylarsonate or sodium dimethyl arsanilate. $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{AsO} \cdot \text{OH} \cdot \text{ONa} \cdot 5\text{H}_2\text{O}$. Sodium dimethyl-arsanilate crystallises in leaflets, is slightly soluble in cold water and in alcohol, more so in hot and in dilute acetic and mineral acids.

p-Amino-phenyl-arsenic-toluene-sulphonate.

This body is a new compound prepared by the Schotten and Baumann reaction by condensing para-toluene sulphonic chloride, $\text{C}_7\text{H}_7\text{SO}_2\text{Cl}$ (a by-product in sulphonating toluene), with sodium arsanilate.

It would have the advantage of splitting up into a comparatively innocuous body in the system—

It is obtainable in a white crystalline condition soluble in hot water.

Trisodium arsenite reacting with *p*-toluene sulphonic chloride yields sodium toluene sulphinate and trisodium arsenate.³⁵ It has been suggested that the chloride first reacts with the alkali, forming sodium hypochlorite, $\text{NaO} \cdot \text{OH}$, which then oxidises the arsenite to arsenate.

1-Carboxy-6-acetaminophenyl-3-arsenic acid.

This has been made³⁶ by oxidising 6-acetaminotolyl-5-arsenic acid in aqueous solution with potassium permanganate. White needles containing 1 molecule of water, melting-point about 230°. Hydrolysed with alkali or acid yields 1-carboxy-6-aminophenyl-3-arsenic acid (anthranil-arsinic acid), $\text{COOH} \cdot \text{C}_6\text{H}_3(\text{NH}_2) \cdot \text{AsO}(\text{OH})_2$, in needles, melting-point 245°, which may be diazotised and coupled with amines and phenol. An aqueous solution of the diazo-sulphate of this body yields 1-carboxy-6-hydroxyphenyl-3-arsenic acid (salicylarsonic acid):

2-Amino-tolyl-5-arsenic acid. $\text{NH}_2 \cdot \text{C}_7\text{H}_6 \cdot \text{AsO}(\text{OH})_2$. Patented.) 2-Amino-tolyl-5-arsenic acid forms a sodium salt, $\text{C}_7\text{H}_5\text{O}_3\text{NAsNa}$, in colourless crystals. It may be acetylated, forming the body, $\text{NHAc} \cdot \text{C}_7\text{H}_6 \cdot \text{AsO}(\text{OH})_2$. This is oxidisable with alkaline permanganate into 2-acetylaminocarboxyphenyl-5-arsenic acid,

On diazotising, this substance is converted into 2-hydroxy-carboxyphenyl-5-arsenic acid,

in colourless needles. To produce the 2-amino-tolyl-5-arsenic acid 23 parts of arsenic oxide and 130 parts of orthotoluidine (*i.e.*, about ten times as much toluidine as is required) may be heated together. There is some spontaneous heat evolution before solution is effected. The following indicates the acetylation:

and the following the oxidation with potassium permanganate:

Diazotising is then effected by treating with sulphuric acid and sodium nitrite.

Amino-naphthyl-arsenic acid.³⁷ $\text{NH}_2 \cdot \text{C}_{10}\text{H}_6 \cdot \text{AsO}(\text{OH})_2$. Is prepared on lines corresponding with arsanilic acid by heating α -naphthylamine with α -naphthylamine arsenate at 200°C.; in other words, heating arsenic acid with an excess of α -naphthylamine—

Naphthylamine 230 parts with arsenic acid 23 parts and water sufficient to dissolve were heated to 200° for two hours and treated with sodium hydroxide in the customary manner, passing through the acid stage to purify. The salt was ultimately obtained in pinkish-coloured crystals.

Dicamphoryl arsenic acid.—Quite recently Dr. Morgan³⁸ and Miss Micklethwaite have described this body, made by condensation of arsenious chloride with sodium camphor in dry toluene, a monobasic acid of formula $\text{C}_{20}\text{H}_{30}\text{O}_4\text{AsH}$ being ultimately obtained—*i.e.*, $(\text{C}_{10}\text{H}_{15}\text{O})_2\text{AsO} \cdot \text{OH}$ —almost insoluble in water, readily in benzene, chloroform, &c. The alkali salts are, however, extremely soluble. The author has repeated these experiments.

It is difficult to generalise on the effects which all the foregoing bodies would have on the system. So far as the organic radicle is concerned, if its importance is not outweighed by the arsenic and the arrangement of that element in the molecule of the substance, one may point out that in general, fatty bodies tend to give rise to tremor, convulsions, and paralysis, whilst aromatic bodies produce anaesthesia. Further generalisations³⁹ as to benzene compounds are that—

- (i.) Those containing hydroxyl are antiseptic.
- (ii.) Those containing an amido group or an acid amide are hypnotic.
- (iii.) Those containing an amine and an alkyl are analgesic.

Contrary to the fact that fatty acids are as a general rule easily oxidised in the system, the benzene ring in a medicinal chemical is rarely broken up. Benzene itself is oxidised to phenol. Naphthalene is eliminated as a glycuronic derivative.

It is of interest to recall that arsenic derivatives lose their physiological characteristics on being converted into salts of arsonium bases. These possess a strong curare-like action (paralysing ends of motor nerves of muscles). This occurs, it will be noticed, simultaneously with a change from the 3 to the 5 valent atom.

Iodoform; [Alleged] Formation of —, from carbon dioxide in presence of ammonia. A. Labat. J. Pharm. Chim., 1909, 30, 107–109.

It is found that the supposed formation of small quantities of iodoform by the action of iodine on carbon dioxide in presence of ammonia as stated by Guerin (this J., 1909, 220), does not occur. The iodoform found is derived, not from the carbon dioxide, but from a trace of a ketonic impurity, probably acetone, in the liquid ammonia. It is not invariably formed under the conditions of the

experiment, with all solutions of ammonia; and when produced, is obtained with equal facility, and in the same quantity, by the action of iodine on the ammonia alone, without the intervention of any carbonic acid gas.—J. O. B.

Anthranol; *Some reactions of* ——. R. Padova. *Comptes rend.*, 1909, **149**, 217—220.

When anthranol is boiled with a solution of phenylchloroform in toluene, hydrochloric acid is evolved and dichlorobenzylanthrone, is produced which crystallises from acetone in small, slightly grey prisms melting at 158°—159° C. When heated with pyridine, this substance loses a molecule of hydrogen chloride and forms *o*-chlorophenylanthraquinomethane. This substance crystallises in small prisms with a faint rose colour, gives a dark red coloration with concentrated sulphuric acid and melts at 130°—131° C. Arylanthramines, $R.NH.C_{11}H_9$, can be formed by heating anthranol with excess of arylamines. Phenylanthramine melts at 197°—198° C.; *o*-naphthylanthramine at 199°—201° C., *β*-naphthylanthramine at 213° C. Phthalylideneanthrone can be formed by heating phthalyl chloride in xylene with anthranol. It crystallises in transparent brown leaflets, melting at 262°—264° C. If anthranol be treated with phenanthrenequinone in acetic acid, oxidation takes place and dianthrone, decomposing at 232°—250° C., is produced. When diphenylanthraquinomethane (anthrafuchsone) is reduced with zinc dust and acetic anhydride, it yields acetoxy-10-anthryl-9-diphenyl-methane, melting at 228°—229° C. The solutions of this substance have a strong violet fluorescence.—F. SHDN.

Nitrosobenzene; *New method of preparing* ——. B. Oddo. *Gaz. chim. ital.*, 1909, **39**, I., 659—661.

NITROBENZENE can be obtained, in a yield of 56 per cent. of the theoretical quantity, by the action of nitrosyl chloride on phenyl-magnesium bromide. The nitrosyl chloride is passed into a solution of phenyl-magnesium bromide in anhydrous ether, contained in a flask fitted with a reflux condenser, until it is no longer absorbed. The product is treated with ice and then distilled with steam. The nitrosobenzene is purified by crystallisation from ether. The nitrosyl chloride is preferably prepared by the method of Francesconi and Bresciani (*Gaz. chim. ital.*, 1904, **34**, II., 13), based on the direct union of chlorine with nitric oxide by means of the catalytic action of carbon. It can be preserved in the form of a solution in anhydrous toluene, from which it is expelled by warming.—A. S.

Phenol; *Oxidation of* ——. *Effect of some forms of light and of active oxygen upon phenol and anisol.* H. D. Gibbs. *Philip J. Sci. A.*, 1909, **4**, 133—151.

PURE phenol remains colourless in the sunlight when in contact with indifferent gases, but becomes coloured in the presence of oxygen (this J., 1909, 326). The rate of coloration is slow at the ordinary temperatures, but is fairly rapid at the boiling point of phenol. Oxidation is the cause of the coloration, and quinol, quinone and catechol are produced, and probably, phenoquinone. Active oxygen, that is, ozone or the oxygen liberated at the anode of an electrolytic cell, reacts easily, producing the above-mentioned substances besides glyoxylic acid and carbon dioxide. Glasses which have the most complete ultra-violet absorption retard the reaction of sunlight in the greatest degree. Ozone could not be detected in pure dry oxygen exposed to sunlight. Phenol methyl ether is not coloured by ozone, oxygen, or sunlight. In order to obtain perfectly pure phenol, it must be distilled out of contact with oxygen.—F. SHDN.

Hydroxylamine; *Alkalimetric determination of* ——. A. Stähler. *Ber.*, 1909, **42**, 2695—2696.

THE hydroxylamine is reduced with titanous chloride or titanous sulphate solution, and the resulting ammonia distilled into *N*/10 acid which is then titrated back. The method may be also used for all nitrogenous organic compounds which are reduced by titanous chloride or sulphate, forming volatile amines. The reduction is

carried out in mineral acid solution, the titanous salt being added with shaking until a permanent pink coloration is produced, and the ammonia distilled in the usual manner after addition of potassium hydroxide solution in excess; the titanium hydroxide which is then precipitated, should be of a bluish colour.—E. F.

Primary, secondary, and tertiary alcohols; *The Sabatier-Senderens test for distinguishing between* ——. G. B. Neave. *Analyst*, 1909, **34**, 346—348.

ACCORDING to Sabatier and Senderens (this J., 1903, 577, 657), by the catalytic action of finely-divided copper at 300° C., primary alcohols yield hydrogen and aldehydes, secondary alcohols yield hydrogen and ketones, and tertiary alcohols yield water and unsaturated hydrocarbons. In the author's experiments, the vapours issuing from the tube containing the copper were condensed, and portions of the distillate were treated with:—(1), a solution of magenta decolorised by sulphur dioxide: red coloration indicates aldehydes; (2), a solution of semicarbazide hydrochloride and potassium acetate: ketones give a white precipitate; (3), bromine: unsaturated hydrocarbons cause decolorisation. The test was found to be satisfactory in the case of the 13 primary, 9 secondary and 8 tertiary alcohols examined. The method is useful for the preparation of the corresponding aldehydes from ethyl and normal propyl alcohols, a yield of about 50 per cent. being obtained in the former case.—A. S.

Bismuth salicylate; *Determination of free salicylic acid in* ——. J. B. P. Harrison. *Brit. Pharm. Conf.*, Newcastle, July, 1909.

IN order to determine the free salicylic acid in bismuth salicylate, 1 gm. of the salt is shaken up with 10 c.c. of methylated ether, sp. gr. 0.720, the liquid filtered, evaporated to small bulk on the water bath, and then allowed to evaporate spontaneously. The residue is dissolved in 0.5 c.c. of distilled water and the free salicylic acid determined colorimetrically by means of ferric chloride. The amount of free acid extracted in this way is about one-half of that actually present. 10 grms. of the bismuth salt, containing known amounts of free salicylic acid were extracted in a Soxhlet apparatus. It was found that chloroform and ether of sp. gr. 0.720 were the only satisfactory solvents. Chloroform extracts the whole of the free acid and does not decompose the salt, but it requires a longer time. Ether is quicker, and although it decomposes the bismuth salt, does so to a constant amount. Evaporation of the solvent can be avoided by shaking it with a known volume of standard alkali, neutralising and determining the salicylic acid colorimetrically, but this method is not generally applicable.—F. SHDN.

Antimonium sulphuratum. F. H. Alcock. *Brit. Pharm. Conf.*, Newcastle, July, 1909.

COMMERCIAL *Antimonium Sulphuratum* contains sulphur in various forms, some of which interfere with the uses of this compound. The sulphur may be present in the free state, as sulphuric acid, calcium sulphate, sulphide or thiosulphate, or as the normal antimony trisulphide. Calcium phosphate has also been found, and sodium salts. The test suggested by Tilden should not be forgotten, namely, that antimony sulphide should impart nothing to water.—F. SHDN.

Antimony in its sulphide preparations; *Determination of* ——. D. L. Howard and J. B. P. Harrison. *Brit. Pharm. Conf.*, Newcastle, July, 1909.

THE following method for the determination of antimony can be applied to *Antimonium Sulphuratum*, and the golden sulphide of antimony. 0.5 gm. of this substance is weighed into a 60 c.c. nickel crucible and mixed with 4 grms. of sodium carbonate and 4 grms. of sodium peroxide. The whole is covered with a thin layer of peroxide, and carefully heated at first with a very small flame. The heating is then to be increased till the contents have completely melted. The melted substance is dissolved in a small quantity of water, and sufficient hydrochloric acid added to bring the antimony into solution. The liquid is heated to drive off all chlorine and made up to

50 c.c. If the black sulphide is being analysed, 3 grms. each of sodium carbonate and peroxide are needed for each 0.5 gm. of substance. The sodium carbonate is employed as a diluent or moderator of the action of the peroxide. 100 c.c. of the clear liquid are filled with potassium metabisulphite, made alkaline with phenolphthalein with sodium hydroxide, and tartaric acid is added till the precipitate first formed is redissolved. Three grms. of sodium bicarbonate are added, and the titrimony estimated by titrating with $N/10$ iodine solution. The sulphur is determined by precipitating the clear liquid with barium chloride in the usual way.

—F. SHDN.

Diphenylcarbazine; Use of symmetrical — in volumetric analysis. Determination of mercury in mercurous salts. B. Oddo. *Gaz. chim. ital.*, 1909, **39**, I., 666—671.

THE author uses as an indicator for the determination of the end point of the titration of mercurous salts with sodium chloride solution, symmetrical diphenylcarbazine $(C_6H_5)_2N.H.NH.C_6H_5.CO$, which has already been proposed by azeneuve (this J., 1900, 1007, 1040) as an analytical agent, and has been used by the author in the volumetric determination of copper (this J., 1903, 1066). The intense red coloration produced by mercurous salts with the agent is not affected by small quantities of nitric acid. The process is as follows:—The solution of the mercurous salt is rendered nearly neutral by addition of sodium carbonate, and is then titrated with a $N/10$ solution of sodium chloride, the end of the reaction being attained when a drop of the clear solution no longer gives a coloration on a test-paper prepared with an acetic acid solution of diphenylcarbazine. For the determination of mercurous in presence of mercuric salts, the solution is first treated with a known excess of $N/10$ sodium chloride solution, the mercurous chloride filtered off and washed, and the mercuric salt in the filtrate precipitated with hydrogen sulphide. After filtering, the solution is boiled to expel hydrogen sulphide, and the excess of sodium chloride titrated with mercurous nitrate solution.—A. S.

Amylacetate for celluloid factories in the Netherlands. Bd. of Tr. J., July 29, 1909. [T.R.]

DUTCH Royal Decree, dated the 30th June, provides for the duty-free admission under conditions prescribed in the Decree of the 11th August, 1908, of amylacetate for use in the manufacture of articles of celluloid.

Camphor exports of Japan. For. Off. Ann. Series, 1909. [T.R.]

THE figures for 1908 show a reduction from £513,000 to £10,000, as well as a decline in quantity from 1,820 to 1,076 tons. Meanwhile Chinese camphor and the various kinds of synthetic camphor which are being produced continue to prove most formidable competitors.

PATENTS.

Crystallized crystals of laxative salts; Production of —. T. Kerfoot, Ashton-under-Lyne. Eng. Pat. 15,306, July 20, 1908.

SALTS which possess laxative properties, such as sodium phosphate or phosphate, or magnesium sulphate, are rendered soluble by recrystallising them from a solution of one or more essential oils in water. The essential oils used could possess antiseptic properties, and may be used in approximately saturated solution. Pine oil and cinnamon oil are mentioned as being especially suitable.—T. F. B.

Pharmaceutical preparation [ergot] and process for obtaining the same. Knoll und Co., Ludwigshafen, Germany, Eng. Pat. 27,038, Dec. 12, 1908. Under Int. Conv., Dec. 23, 1907.

ERGOT and its extracts soon decompose and cannot be kept in stock longer than a year. According to this invention a permanent product, which retains the full effect of the fresh drug, is obtained from the aqueous extract of ergot, after removal of the fat, by neutralising, concentrating, and then treating it exhaustively with alcohol and ether of high percentage. By this treatment inactive substances separate out together with very small proportions of the active principles, whilst the main portion of the latter remains in the alcohol-ether solution. The latter is concentrated and dried, preferably *in vacuo*, and after admixture with lactose or other suitable substances, it is made into a permanent preparation.—J. F. B.

Therapeutic compound [from laudanum]; Manufacture of a —. H. S. Wellcome, London, and F. L. Pyman, Dartford. Eng. Pat. 314, Jan. 6, 1909.

WHEN laudanum (*N*-methyltetrahydropapaverine) is oxidised, e.g., by means of manganese dioxide and sulphuric acid, veratraldehyde is formed, together with a new base, 2,3-methylaminoethyl-4,5-dimethoxybenzaldehyde. The veratraldehyde is removed from the acid oxidised mixture by filtering, neutralising with sodium carbonate, again filtering, and extracting with benzene; the alkaline solution is mixed with sodium hydroxide and extracted with benzene, the benzene extract being shaken with dilute hydrochloric acid to neutralise the base. The new substance forms colourless needles, of m. pt. 123°—124° C. Its hydrochloride melts at 61°—62° C., its aurichloride at 169° C., and its picrate at 169°—170° C.—T. F. B.

Physiologically active base; Method of manufacture of a — [*p*-Hydroxyphenylethylamine]. H. S. Wellcome, London, and G. Barger, Herne Hill. Eng. Pat. 1560, Jan. 22, 1909.

WHEN *p*-hydroxybenzylcyanide is reduced, *p*-hydroxyphenylethylamine is produced. For example, 5 grms. of the above cyanide are dissolved in a little boiling alcohol, and 7—10 grms. of sodium are gradually added, the solution being kept boiling and concentrated. When the sodium is dissolved, the solution is neutralised with hydrochloric acid, evaporated to dryness, and extracted with absolute alcohol. The free base is obtained by rendering the solution of the hydrochloride alkaline with sodium carbonate, evaporating to dryness *in vacuo*, and extracting with boiling xylene, in which the base is slightly soluble. It is readily soluble in water and in warm alcohol; its m. pt. is 161° C., and it distils at 161°—163° C. (2 mm. pressure) and at 175°—181° C. (8 mm. pressure).—T. F. B.

Medical preparation [nuclein rich in iron] from yeast and process of manufacturing the same. A. Ascoli, Milan, Italy. Eng. Pat. 5571, March 8, 1909. Addition to Eng. Pat. 21,820, Oct. 15, 1908.

THE precipitate obtained by treating yeast according to the original patent (see Ger. Pat. 194,950; this J., 1908, 644), is washed and dried at about 50° C., with or without a vacuum. The dry product obtained is tasteless and stable. If, in the preparation of the product, a more dilute solution of alkali has been used than that described in the original patent, the temperature of drying must be raised.—T. F. B.

Tartar; Process for treating substances containing crude —, in order to render colouring matter insoluble. V. Garin and F. David. Second Addition, dated Mar. 7, 1908, to Fr. Pat. 374,276, April 12, 1906. (See this J., 1907, 778.)

PROLONGED boiling (e.g., for about 45 mins.), after treatment with formalin, may replace the drying specified in the principal patent.—F. SODN.

Surrender of Letters Patent under Section 26 (3) of the Patents and Designs Act, 1907. London Gazette, Aug. 13, 1909.

THE Comptroller-General has, on the application of the inventors, revoked the Letters Patent granted to Knoll, Daeger and Knoll for "Manufacture of santalol esters from sandal wood oil," No. 17,511, of Feb. 10, 1905 (this J., 1906, 233).

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENT.

Photographic reproduction of colours. E. C. G. Caille, Levallois-Perret, France. Eng. Pat. 15,050, July 15, 1908. Under Int. Conv., July 16, 1907.

A SCREEN for colour photography is prepared by superposing on a transparent surface, three transparent layers, one layer being ruled with parallel lines and the others with dots to fill the spaces between the lines; the layers are coloured orange, green, and violet respectively, and the screen is provided with guide-marks. An opaque "support" is then prepared to correspond exactly in ruling to the screen, the patterns being coloured with the colours complementary to those on the screen. This support is covered with a silver bromide-gelatin emulsion. The object to be reproduced is photographed on a photographic plate through the screen, and the resulting negative is printed in the usual manner on a support prepared as above, which is then developed and fixed. The result is a reproduction in colour of the original, but covered by a series of black dots consisting of reduced silver. These are bleached by means of a 1—2.5 per cent. solution of mercuric chloride, and the print is dried, without washing. Cupric chloride, or other chloride capable of converting silver into its chloride, may be used in place of mercuric chloride. Certain modifications of the above process are also described.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Explosives; Thirty-third Annual Report of H.M. Inspectors of —. 1908.

Factories and magazines.—The number of factories under continuing certificate was 33 and under licence 105. The number of magazines under continuing certificate was 92 and under licence 348. During the year 154 visits were paid to factories, and 436 to magazines. There was an objection, during the course of the year, by the local authorities at Perranporth, Cornwall, to the granting of an amending licence for the storage of cordite. An appeal was made against this refusal, and an inquiry was held by one of the inspectors, with the result that the appeal was allowed.

Importation.—The amount of foreign blasting explosives containing nitroglycerin imported during the year was 1,086,205 lb., but of this quantity 656,250 lb. were transhipped to other countries. The amount of blasting explosives imported, not containing nitroglycerin, was 6,100 lb. The number of detonators imported was almost 18,000,000, but of this number almost 2,000,000 were immediately transhipped for other countries. 399 tons of fireworks were imported during the year.

Accidents.—The number of accidents from fire or explosion, of which the Department had cognisance during the year was 392, causing 34 deaths, and injuring 402 persons. The number of deaths (3) from accidents by fire or explosion in the manufacture of explosives, was much below the average for the decade (7).

Heat test committee.—A meeting of the officials of the explosives department and representatives of the trade was held on Dec. 15, 1908, to consider the question of the heat test for explosives. The general feeling of the meeting is stated to have been:—(1). That although the heat test was second to none as regards reliability; and as a test of purity in manufacture was, by reason of its

convenience and adaptability to all natures of nitro compounds, practically indispensable, it was undoubtedly highly desirable that where important interests were involved, a verdict of rejection should not depend on single test. (2). That, if substantial financial assistance were to be forthcoming from the trade, it was of the utmost consequence that any check test or tests should be formulated under the *auspices* of a body of experts of unquestioned authority such as a joint committee representing the Home Office, War Office, Admiralty, and lastly, the trade itself.

Chemical Advisers' Report.—Messrs. Dupré report that out of 416 samples examined, 58 were rejected. The rejections were for the following reasons, and in the numbers stated:—Heat test (16); exudation (8); containing mercury (10); incorrect composition (24); too sensitive (2).

There was a drop in the number of samples received from the Customs, and also in the number of samples examined in connection with the Home Office testing station at Woolwich. 56 tests for mercury were made and 183 special tests on gun-cotton. As regards the rejection of permitted explosives for incorrect composition, it is stated that this number is considered to be moderate considering the amount of these explosives now used, the complexity of the composition in many cases, and the smallness of the margin that can be allowed for error of manufacture.

The fund provided by the Treasury for the investigation into the heat test and other stability tests has been exhausted. A large amount of work has been done and Messrs. Dupré hope to have an opportunity of publishing all the results at a future date. In regard to the question of mercury in explosives, as stated in the report for 1907, it was found that 0.001 mgrm. of mercury under favourable conditions, has a marked influence on the heat test. With the conditions under which the spectroscopic test is worked, less than 0.01 mgrm. cannot be detected with certainty. Considering the explosive for which the smallest quantity is taken for the heat test, and the largest for the spectroscopic test, *viz.*, cordite, one thousandth of a 0.001 mgrm. of mercury, or a quantity sufficient to affect the heat test, on the 25 grains taken for this test, is, very approximately, 1 part in 2,000,000; while 1 part in 2,000,000 on the 15 grms. employed for the spectroscopic test is very nearly 0.01 mgrm., or the smallest quantity that can be detected. The two tests are therefore, in this case, strictly comparable, while in the case of all other explosives, under the tests at present prescribed, the heat test is the more sensitive. When considering the amounts of materials that might influence the heat test, their action under the most favourable conditions must be considered, such, *e.g.*, as would obtain if mercuric chloride in solution, were painted on the outside of the explosive. It is considered that the presence, in however minute a proportion, of an unnecessary ingredient, which may be objectionable, justifies the rejection of the material containing it, regardless of the quantity required to do actual harm. If it can be proved that the precautions necessary to avoid the presence of such minute traces would seriously hamper the trade as a whole, a compromise might become necessary. The results of a very large number of tests, made on many samples to which there was no reason to suspect a deliberate addition of mercury, have shown that it is, to say the least, highly improbable that the spectroscopic test, as carried out, will detect such mercury as may find its way into the explosive in the ordinary process of manufacture. A large amount of work on the stability and purification of gun-cotton was carried out and many interesting and suggestive results obtained, but no definite statement could, for the moment, be made upon this matter.

Testing station at Woolwich.—Captain Deaborough reports that eight explosives were submitted to the official test. Seven of these tests were successful with the result that one new explosive which was tested three times on account of variation in the percentage of the ingredients and in the nature of the wrapper, was added to the list. A table in the report shows the ignitions of firedamp, or coal dust, which were brought to the notice

of the department during the year. One of these was particularly noteworthy in that it occurred with the use of carbonite. This explosive, when tested by the instemmed shot system gives the result that a charge of 1000 grms. fails to ignite the most sensitive gas mixture. In the particular case, at Whitwood Colliery, a charge of under 350 grms. ignited firedamp; no coal dust was involved. It is not implied that this proves that the Continental system of testing is wrong; but it demonstrates that the advocates of that system of testing explosives are not warranted in making the statement that it is always safe to use charges not exceeding the *charge limite*. This is the first recorded instance, in this country, of an ignition of firedamp by carbonite. An ignition occurred at the Glencoe Colliery in Natal, on Feb. 13, 1908. According to the report of the Commission appointed to inquire into the accident, the ignition was occasioned by the firing of a charge of 6 oz. (about 70 grms.) of carbonite, in a shot hole 2 feet 9 inches in length, stemmed to the mouth with damp sandy loam. A shot had been fired the previous day, but had only "chambered" the coal leaving the face and stemming intact. The shot which caused the ignition was planted 5 inches from the former shot-hole. There was evidence to show that the coal, which it was intended to bring down, had apparently not been loosened or shaken by the shot fired on the previous day. On firing the shot, eight persons were injured by the resulting ignition; three of them subsequently succumbed to their injuries. The coal was also found to be on fire. Subsequently explosions occurred which caused great loss of life.

The following list gives the amount of explosives used in Great Britain in mines and quarries from details supplied by the Mines Department:—

Explosive.	Quantity used.	Percentage of total.
	lb.	
Permitted explosives	8,297,738	26.9
Unpowder	18,736,168	60.9
Ignite	2,737,468	8.9
Fast gelatin, dynamite, and gelatin dynamite	668,401	2.2
Beddite	249,996	0.8
Various	103,952	0.3
Total	30,793,723	100.0

—G. W. McD.

Explosives in coal mines. Home Office Order, July 3, 1909, No. 748.

The following is a complete list of the names of permitted explosives as defined in the Schedules to the Explosives in Coal Mines Order of the 17th December, 1906, as amended by the Orders of the 8th April, 1907, of the 6th May, 1908, of the 20th August, 1908, of the 2nd April, 1909, of the 20th April, 1909, and of the 3rd July, 1909:—

Explosives in 1st Schedule.

Abbeite.	Dominate.	Permitite.
Ablonite.	Dragonite.	Permonite.
Amasite.	Electronite.	Permonite II.
Ammonal.	Excellite.	Phoenix Powder.
Ammonal B.	Extra Carbonite.	Pit-ite.
Ammonite.	Faversham Powder.	Rexite.
Amvis.	Fracturite.	Ripping Ammonal.
Amphosite.	Good Luck.	Rippite.
Arkite.	Haylite No. 1.	Roburite No. 3.
Bellite No. 1.	Kolax.	St. Helen's Powder.
Bellite No. 3.	Kynite.	Samsonite.
Bobbinate.	Kynite Condensed.	Stow-ite.
Bronite.	Minite.	Thunderite.
Cambrite.	Monobd Powder.	Titanite.
Carbonite.	Negro Powder.	Titanite No. 1.
Cellite.	Nobel Ammonia Powder.	Tutol.
Cellite.	Nobel Carbonite.	Victorite.
Dydlite.	Nobel Carbonite.	Virtite.
Colliery Steelite.	Normanite.	Westfalite No. 1.
Cornish Powder.	Oaklite No. 1.	Westfalite No. 2.
Curtisite.	Oaklite No. 2.	Withnell Powder.
Hammerite A.	Odite.	

Explosive in 2nd Schedule.

Bickford's Igniter Fuze.

The Secretary of State has made an Order adding the following explosives to the Schedule of the "Explosives in Coal Mines Order of Dec. 17th, 1906":—

Nobel Ammonia Powder.

Ingredients.	Parts by weight.	
	Not more than	Not less than
Ammonium nitrate	86	82
Nitroglycerin	9	7
Wood-meal (dried at 100° C.) ..	8	6
Moisture	2	0.5

provided that the cases are thoroughly waterproofed with ceresine and resin, and that the explosive shall be used with a detonator of not less than No. 6 strength (i.e., one containing 15 grs. of a composition consisting of 80 per cent. of mercuric fulminate and 20 per cent. of potassium chlorate).

Samsonite.

Ingredients.	Parts by weight.	
	Not more than	Not less than
Nitroglycerin	60	57
Nitro-cotton	4	3
Potassium nitrate	19	17
Wood-meal (dried at 100° C.) ..	7	5
Moisture	1.5	—
Ammonium oxalate	14.5	12.5

provided that the explosive be contained in a non-waterproofed wrapper of parchment paper, that it be used only with a detonator of not less strength than No. 6, and that, if frozen, it be thoroughly thawed before use.

Titanite No. 1.

Ingredients.	Parts by weight.	
	Not more than	Not less than
Ammonium nitrate	88	85
Trinitrotoluol	8	6
Curcuma charcoal (dried at 100° C.)	6.5	4.5
Moisture	1	—

provided that the explosive be contained only in a case of stout paper thoroughly waterproofed with paraffin and that it be used only with a detonator of not less strength than No. 6.

Nitroglycerin; The velocity of decomposition of — by heat. R. Robertson. J. Chem. Soc., Trans., 1909, 95, 1241—1248.

THE mode of decomposition of nitrocellulose at temperatures below the exploding point, has been worked out by Will (this J., 1901, 609; 1902, 1470, 1554), who gave an equation expressing the quantity of nitrogen disengaged as a function of the temperature. Further work on this subject has been done by the author (this J., 1902, 819; 1907, 639). In the present communication

the decomposition of nitroglycerin is dealt with, when free from the catalytic accelerative action produced by its volatile products of decomposition. The difficulties due to the volatility of nitroglycerin, and the risks of explosion were overcome by the use of the apparatus figured. Jena glass wool, soaked in 0.3 to 2.5 grms. of nitroglycerin dissolved in acetone, which was subsequently evaporated off was placed in the horseshoe-shaped tube, closed by a ground and mercury-sealed plug. A current of carbon dioxide could be sent down the right-hand spiral, through the glass wool, and up

the other spiral, or *vice versa*, according to the position of the stopcocks. At the upper end of the apparatus is a slip joint, between which and a supporting pivot at the bottom, the whole apparatus could be rotated about its axis. The carbon dioxide used contained only 0.02 per cent. of gas unabsorbed by caustic potash solution and, to eliminate any oxygen, was passed over red-hot copper. It was passed through at the uniform rate of 1000 c.c. per hour. The spiral, *s*¹, was immersed in an oil-bath, the temperature of which was maintained uniform by means of a stirrer. It served as a pre-heating worm for the current of carbon dioxide. The spiral, *s*², above the heated oil, and protected from it by asbestos cards, was cooled by an air blast. It served to condense any volatilised nitroglycerin. After a suitable period, the apparatus was rotated through 180 degrees, when the spirals exchanged functions. Any nitroglycerin which might have condensed in *s*² was thus restored to the system. The gaseous products of decomposition were led off, for examination, through the slip joint by means of fixed glass tubes, the use of indiarubber being thus avoided. As a precaution against the carrying over of nitroglycerin, the gases were passed through an ice-cooled worm immediately on leaving the decomposition apparatus. The mixture of carbon dioxide, of which the volume was known, and volatile products of decomposition was usually passed through an observation tube, in which the concentration of nitrogen peroxide was determined by the spectroscopic method, and from this the weight of nitrogen disengaged as nitrogen peroxide was calculated. In most cases the gases issuing from the observation tube were then passed through hot reduced copper asbestos and copper oxide asbestos and into a gas burette containing caustic potash solution, where the unabsorbed nitrogen was measured every quarter of an hour. The following conclusions were arrived at:—

(1). The disengagement of nitrogen peroxide proceeds in a perfectly uniform manner. Thus from 0.5 gram. of nitroglycerin at 120° C., nitrogen peroxide was found, by the spectroscopic method, to be present in the stream of carbon dioxide in the following concentrations for 16 successive quarter hours: 0.04, 0.07, 0.09, 0.11, 0.11, 0.12, 0.12, 0.12, 0.13, 0.13, 0.12, 0.12, 0.12, 0.12.

These results agree with the volume of nitrogen, after combustion, unabsorbed by a solution of caustic potash.

(2). The nitrogen is disengaged for the most part, not entirely as nitrogen peroxide, and the estimation of the nitrogen existing as such, by the spectroscopic method agrees with the results of estimation by combustion and other methods. In this respect nitroglycerin differs from gun cotton, from which the nitrogen disengaged as nitrogen peroxide at 135° C. amounts to only about 40 per cent. of the total nitrogen. The following table shows the results obtained.

Disengagement of nitrogen from 2.5 grms. of nitroglycerin

Temperature °C.	Total nitrogen (by combustion).	Nitrogen as peroxide (spectroscopic).
135	4.87	4.33
130	2.72	2.90
124.9	1.62	1.57
119.8	0.74	0.80
115.0	0.36	0.39
110.2	0.29	0.20
105.0	0.10	0.086
100.5	0.044	0.043
95.0	0.021	0.024
90.3	0.009	0.010

(3). The rate of decomposition is a function of the temperature and increases from 95° C. to 125° C., being doubled in a rise of 5° C.

(4). Nitroglycerin has a higher rate of decomposition than gun cotton under similar conditions and at the same temperature.—G. W. McD.

PATENTS.

Explosives. B. E. D. Kilburn, London. From C. Pieper Berlin. Eng. Pat. 12,506, July 27, 1908.

The claim is for a mixture in equi-molecular proportion of starch, ammonium perchlorate, and sodium or potassium nitrate. A suitable binding material may be added if desired.—O. R.

Volatile liquids from smokeless powder manufacture, &c., Recover of —. Fr. Pat. 397,791. See V.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Vacuum distillation apparatus, with electrically heated delivery tube for solid substances having high or low melting points. J. Bredt and A. van der Maaren-Jansen. Annalen, 1909, 367, 354—358.

The authors have devised a distilling apparatus by means of which choking of the delivery tube by the substance solidifying can be avoided. It consists of a distillation flask, B, provided with a second neck, *f*, in line with the delivery tube, *aa*₁. The delivery tube, *a'a*, is connected by a cork to the receiver, E. The heating arrangement, A, shown separately, is formed by wrapping a nickel wire, 1.75 metres long and 0.2 mm. diameter, round a glass rod 2 mm. thick. This rod is held in a sealed tube of 4.5 mm. outside diameter, and is fastened at one end only to allow for expansion. The heating arrangement must be as long as the delivery tube, which in this case was 6 mm. internal diameter. The connecting wires, *a/a*₁ and *a/a*₂, are made of platinum 0.3—0.4 mm. thick, so as not to become heated by the electric current. In order to control the temperature of the delivery tube, the glass tube, C, contains another similar heating arrangement

in the same circuit and a thermometer. By means of suitable resistances the delivery tube can be heated to any temperature up to 300°C .—F. SHDN.

PATENT.

Measuring and recording device for apparatus for gas analysis. J. Fehner. Ger. Pat. 211,739, Dec. 14, 1907.

With this apparatus the quantity of a gas is measured by determining the weight of a given liquid displaced by the gas. The gas to be measured passes into a vessel, from which it displaces the liquid through a siphon tube to a vessel resting on one arm of a balance, the other arm of which may be connected to a recording device. In order that the amount of liquid to be weighed shall not be too large, a vessel may be disposed just in front of the siphon tube: a definite portion of the displaced liquid fills this vessel, and only the remainder passes through the siphon tube and is weighed.—A. S.

INORGANIC—QUALITATIVE.

Saiacal and quinine as reagents for hydrogen peroxide. Denigès. See XX.

INORGANIC—QUANTITATIVE.

Electro-analytical precipitations and separations; Some rapid —. H. Alders and A. Stähler. Ber., 1909, 42, 2685—2695.

In the separation of liquid amalgams a thin-walled glass flask is used, of 75 to 100 c.c. capacity and 10 mm. diameter in the neck. The bottom of the flask is markedly concave and three platinum wires 0.6 to 0.7 mm. thick are sealed through the outer edge of the base. The cell itself weighs about 20 grms. and holds about 10 grms. of mercury which forms a ring round the edge of the base. The anode consists of iridio-platinum wire, 0.5 mm. thick wound into a horizontal coil at the bottom. The vertical portion of the wire is 10 cm. long, and passes through a small funnel, which serves to prevent loss of liquid during the rotation of the anode. The cell is placed on a sheet of bright copper in electrical contact with the platinum feet. The anode is rotated 400 to 600 times a minute. Generally a current of 3 to 4 ampères is used for electrolysis. Mercury can be rapidly and accurately determined in this cell from solution in either nitric or sulphuric acid. After connecting up with the source of current, the solution is gently warmed and so much nitric acid added, whilst stirring, that a current of 3 to 4 amps. is obtained at 5 to 6 volts. In 10 minutes

a drop of the electrolyte is tested with ammonium sulphide solution, and the current passed for a further 5 minutes when no more mercury can be detected. The cell is washed with hot water during passage of the current, with use of a pipette, then washed with alcohol and ether and dried for 15 to 30 minutes in a vacuum desiccator. The results are said to be very accurate. Similar experiments were tried with zinc: from solutions of the sulphate, with lead: from a mixture of nitric and phosphoric acids, and with iron: from sulphuric acid solution of ferric sulphate, but in all these cases the amalgam which is formed, oxidises on the surface during washing. For the determination of copper, from solution of the sulphate, and silver, from the nitrate, the method gave very accurate results, and was in every way suitable. Mercury could be accurately determined, from solution of the chloride, in presence of arsenic. One c.c. of strong nitric acid was first added to 100 c.c. of the liquid, which was then electrolysed at 5 to 5½ volts, E.M.F. for 15 minutes; sodium hydroxide solution was then added until the liquid was only faintly acid, the current continued for a further 5 minutes, and the cell washed out as usual. The mercury was bright and coherent. In the residual liquid the arsenic was determined in the usual manner with magnesia mixture. Both results were accurate. In presence of phosphoric acid, arsenic, selenium and some other substances, lead cannot be determined in the usual manner as dioxide at the anode; if one attempts to deposit it as metal on the cathode, in the presence of reducing agents to prevent formation of the dioxide, a very spongy and oxidisable precipitate is obtained. The authors attempted to determine the lead as liquid amalgam in their apparatus, but without satisfactory result, owing to loss on washing. But they were able to determine this metal rapidly and accurately by deposition simultaneously with a known amount of mercury. To the solution of the lead salt containing a slight excess of nitric acid a known amount of mercury nitrate or chloride was added in solution, together with a few c.c. of strong phosphoric acid solution, and the liquid electrolysed in a platinum dish with stirring, the dish forming the cathode. The electrolysis lasted about 20 minutes, with an E.M.F. of 10 to 11 volts. The dish was finally washed with water, alcohol and ether and dried for 15 minutes in the desiccator. The use of mercurous nitrate was more accurate than that of mercuric chloride. The deposit of lead and mercury was removed from the platinum dish with dilute nitric acid, and this caused a slight loss of platinum. Lead can be accurately determined in this manner in presence of quinquivalent arsenic, if phosphoric acid be added. Otherwise the determination

is carried out in precisely the same manner as in the absence of arsenic. Attempts to determine lead in the presence of antimony and of selenium were not satisfactory.—E. F.

Chromium, copper, nickel, cobalt, zinc, and lead; Indirect volumetric determination of —. A. Bacovescu and E. Vlahuta. Ber., 1909, 42, 2638—2642.

If solutions of chromium, copper, nickel, cobalt, zinc, or lead salts are treated with freshly precipitated manganese carbonate, chromium is precipitated as hydroxide, the other metals as carbonates, whilst an equivalent amount of soluble manganese salt is produced. After filtering off and washing the precipitate, the manganese solution can be titrated and the amount of substituted metal calculated. The salts to be determined should be normal; if free acid be present, this must be neutralised. The manganese solution is titrated with potassium permanganate in presence of zinc sulphate. The authors have tested the method by working with standard solutions of the various metals. In most cases heating for several hours was necessary to effect complete double decomposition, and the method is practicable only in the case of copper, chromium and lead. Manganese hydroxide can also be used for the precipitation and answers for the determination of copper, zinc, chromium, cobalt, and nickel salts. Lead salts cannot be determined with the hydroxide as they form partly soluble double salts. The method is in practice carried out as follows: One to two drops of nitric acid are added to a mixture of equal volumes of approximately *N*/1 solutions of manganese sulphate and potassium hydroxide or carbonate respectively. The liquid is decanted off and the precipitate washed carefully, and is then added to the solution to be determined. After boiling for several minutes, the precipitate is filtered off and washed, and the solution titrated with potassium permanganate. An excess of the manganese salt is necessary and a ratio of 2:1 has been found satisfactory.—R. L.

Copper; Iodometric determination of —. E. V. Videgren. Z. Anal. Chem., 1909, 48, 539—545.

The sample (2—3 grms. of ore) is dissolved in 10—20 c.c. of a mixture of equal volumes of concentrated sulphuric and nitric acids. When sulphuric acid fumes appear, the flask is cooled, 30—40 c.c. of hydrochloric acid of sp. gr. 1.1 are added, and evaporation carried on till spitting begins. Then, 10—15 c.c. of concentrated sulphuric acid are added, and the evaporation can now be carried to complete expulsion of hydrochloric and nitric acids without fear of loss by spitting. Or, for greater security, the evaporation with concentrated nitric and sulphuric acids may be done in a 400 c.c. beaker, and after cooling, an addition be made of 20—30 c.c. of dilute hydrochloric (sp. gr. 1.1) and 20—30 c.c. of dilute sulphuric acid (sp. gr. 1.4), after which evaporation is carried on till sulphuric acid fumes appear. After cooling, the solution is diluted with water; the greater the amount of iron to be reduced and removed, the more water must be added, to allow for loss by evaporation during the heating (for 3 grms. of purple ore, containing say 0.16 per cent. of copper and 60 per cent. of iron, the volume should be 200 c.c.). The solution is now boiled, as Low recommends, with a strip of aluminium sheet, 145 mm. by 25 mm. by 1 mm., till the iron is completely reduced and the copper precipitated (8—30 minutes); the copper comes down in dense flocks, which can be readily washed. The sides of the beaker are washed down with weak sulphuretted hydrogen water, the aluminium strip is similarly washed, the copper allowed to settle to the bottom, the perfectly clear liquid poured off, and the copper washed by decantation with 100—150 c.c. of the sulphuretted hydrogen water. It is now dissolved in a mixture of 20 c.c. each of 3½ per cent. potassium chlorate solution, hydrochloric acid (sp. gr. 1.1) and sulphuric acid (sp. gr. 1.4), per gramme of metal, the solution is evaporated till all chlorine and hydrochloric acid are expelled, cooled, dissolved in water—(for 0.01 gm. of copper, 20—30 c.c., for 0.4—0.5 gm., 100—200 c.c. of water) potassium iodide added, and the iodine titrated as usual. If arsenic or antimony be present,

5 c.c. of 25 per cent. sodium acetate solution must be added before adding potassium iodide. Should the liquid decanted from the precipitated copper not be quite clear, it must be filtered, the filter washed free from iron with weak sulphuretted hydrogen water, the filter broken and the precipitate washed through, 10 c.c. of hot chlorate and acid mixture poured through, the filter washed, the liquid evaporated to about 4 c.c., 20 c.c. of water and 5 c.c. of sodium acetate solution added, and the liquid separately titrated.—J. T. D.

Lead; Volumetric determination of —, and of sulphuric acid in sulphates. B. Oddo and A. Beretta. Gaz. chim. ital., 1909, 39, I., 671—675.

The authors find that the method of determining lead by titration with potassium chromate is greatly improved by using as indicator an acetic acid solution of diphenylcarbazide, which is a very sensitive reagent for chromates (see Cazeneuve, this J., 1900, 1040). The solution containing the lead salt is acidified with acetic acid, or if it contain free mineral acid, is treated with ammonium acetate before titration. The end point is best ascertained by placing on filter paper a drop of the titrated solution and a drop of the diphenylcarbazide reagent, and noting the colour where the drops intersect. In utilising this method of determining lead for the determination of sulphuric acid in sulphates, by precipitating with a soluble lead salt, it is necessary to filter off the lead sulphate, as the reaction, $\text{PbSO}_4 + \text{K}_2\text{CrO}_4 \rightleftharpoons \text{PbCrO}_4 + \text{K}_2\text{SO}_4$, is reversible. The sulphate solution is treated with a known excess of lead nitrate solution, the precipitate filtered off, and washed well with cold water, and the excess of lead in the filtrate determined as described above.—A. S.

Nickel; Separation of — from iron by means of ammonia. V. Hassreidter. Z. angew. Chem., 1909, 22, 1492.

It has previously been shown (Z. angew. Chem., 1908, 21, 66) that by using a concentrated solution of ammonia (sp. gr. 0.90 to 0.92) retention (adsorption) of zinc by ferric hydroxide precipitated from a solution containing iron and zinc may be entirely prevented. In like manner the use of a concentrated solution of ammonia for the precipitation of the iron from a solution which also contains nickel gives a precipitate practically free from nickel. The conditions are shown by examples of which the following are typical:—

Total volume.	Ammonia solution (sp. gr., 0.92).	Iron.	Nickel.	Nickel in filtrate.
c.c.	c.c.	grms.	grms.	grms.
250	200	1	0.25	0.2527
250	200	0.25	1.00	0.0085

—C. A. M.

Nitric acid; Determination of —, by means of nitron. C. Paal and A. Ganghofer. Z. anal. Chem., 1909, 48, 545—555.

The authors have repeated the work of Hes on the influence of dextrin, peptones, and gelatin on the determination of nitrates by means of nitron. Dextrin, added in amounts of 0.5—2.0 grms. to a solution of 0.175 gm. of potassium nitrate in 100 c.c. of water, was found to delay the separation of the nitron precipitate, 16 hours instead of 4 being needed for the purpose, but was without sensible influence on the accuracy of the results. Peptone (0.5 gm. in the same solution) gave results much too high, and on removal of the added peptone by normal lead acetate, by formaldehyde, or by tannin and lead acetate, results sometimes too high and sometimes too low were obtained. Addition of 20—25 drops of sulphuric acid to the peptone-containing solution, however, corrected this, and the results so obtained were quite accurate. Gelatin, up to 0.5 gm., was without sensible influence on the results (save as to duration of the separation), but 1 gm. gave results about 1 per cent. too high. Even when 2 grms. were added, and then removed by tannin and lead acetate to remove excess of tannin, the results,

though low, were sufficiently near for practical use. Some repetitions of the authors' former experiments with meat extracts confirmed their earlier results, and showed that saltpetre in meat can be conveniently determined by means of nitron.—J. T. D.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Sun as source of heat in chemical experiments; The —. A. Stock and H. Heynemann. Ber., 1909, 42, 2863—2866.

The authors point out the advantages to be obtained by using the sun as a source of heat, when the substance to

be heated is contained in a glass vessel from which the air has been completely removed. The heat can be concentrated on the substance itself, so that its support does not need to be specially refractory. By working in a complete vacuum a much higher temperature can be obtained than if air be present, loss of heat by conduction being reduced to a minimum; no interference from foreign gases is to be feared; and any gases evolved can be collected in a pure state for examination. In the authors' experiments, a plano-convex lens of 40 cm. diameter and 50 cm. focal length was fixed in a wooden frame, on a support, so that it could be turned in all directions. On the lower side of the wooden frame was an iron support, to which the flask containing the substance to be heated was fixed. The substance itself was placed in a magnesia crucible, and the flask was connected to a mercury pump. With this apparatus, crystallised silicon (m.pt. 1450° C.) was melted in a few seconds, whilst pieces of copper and cast-iron melted almost instantaneously. With manganese, the flask rapidly became coated with a mirror of the metal. When the junction of a thermo-couple was suspended freely in the centre of the flask, this showed a temperature of 1030° C. *in vacuo* and only 675° C. in an atmosphere of air under otherwise identical conditions. It is proposed to continue the experiments on a much larger scale.—A. S.

Thorium chloride and bromide; Hydrates of —. E. Chauvenet. Comptes rend., 1909, 149, 289—292.

If the hydrated chloride, $\text{ThCl}_4 \cdot 8\text{H}_2\text{O}$, be left under a bell jar at the ordinary temperature, the crystals lose their form, and eventually give the hydrate, $\text{ThCl}_4 \cdot 7\text{H}_2\text{O}$, described by Krüss. When the normal hydrate with 8 mols. of water is heated at 50° C. in a current of hydrogen or dry hydrochloric acid gas, or when it is left for several days in a dry vacuum, the hydrate, $\text{ThCl}_4 \cdot 4\text{H}_2\text{O}$, is formed. By heating the normal hydrate on the water-bath, the chloride, $\text{ThCl}_4 \cdot 2\text{H}_2\text{O}$, is produced, whilst at temperatures above 100° C., an oxychloride, ThOCl_2 , is eventually obtained. The author has been unable to prepare the hydrated chloride containing 9 mols. of water described by Rosenheim and Schilling (Ber., 1900, 977). The normal hydrated thorium bromide, $\text{ThBr}_4 \cdot 12\text{H}_2\text{O}$, obtained by dissolving thorium hydroxide in alcoholic hydrobromic acid crystallises in long needles. When dried under a bell jar it is converted into the hydrate, $\text{ThBr}_4 \cdot 10\text{H}_2\text{O}$, and on exposure in a dry vacuum gives the hydrate of Rosenheim and Lesinsky, $\text{ThBr}_4 \cdot 7\text{H}_2\text{O}$. The existence of a hydrated bromide containing 8 mols. of water is doubtful. When heated at 50° C. the normal bromide is converted into the compound, $\text{Th}(\text{OH})\text{Br}_3 \cdot \text{H}_2\text{O}$, analogous to the chloride, $\text{Th}(\text{OH})\text{Cl}_3 \cdot \text{H}_2\text{O}$, formed as intermediate product on heating the normal hydrated chloride at temperatures above 100° C. The oxybromide, ThOBr_2 , is produced at about 165° C., whereas the corresponding oxychloride is formed at about 250° C.—C. A. M.

Perseulose; Constitution of —. G. Bertrand. Comptes rend., 1909, 149, 225—227.

PERSEULOSE is obtained by oxidation of perseït, a sugar found in the kernels and leaves of *laurus persica*. The author has proved the presence of a ketonic grouping in perseulose by the following reactions:—Perseulose is not oxidised by bromine in the presence of water. When reduced with sodium amalgam in a solution containing a slight excess of sulphuric acid, two alcohols are produced, namely, *perseitol* (m. pt. 188° C., $[\alpha]_D^{20} = +1.20^\circ$), and a laevo-rotatory alcohol which is very soluble in water and alcohol, and probably contains seven carbon atoms, and for which the author proposes the name *perseulitol*. The production of two isomeric alcohols in this way indicates the presence of a ketonic rather than an aldehydic grouping in perseulose.—F. SHDN.

Oxydases; Investigation of —. O. Dony-Hénault. Bull. Acad. Sciences Belg., 1909, 342—409. Bull. Soc. Chim. Belg., 1909, 23, 318—320. (Compare this J., 1908, 823.)

The blue coloration with guaiacum tincture, attributed to the oxydases, is very sensitive to alkalis; it is caused

by alkali associated with small quantities of mineral substances, particularly manganese, and is destroyed by the presence of the slightest excess of acid. The reaction is neither more nor less characteristic of oxydases than the oxidation of hydroquinone under similar conditions. The reaction of oxydases with guaiacol-red coloration and formation of a precipitate, considered by Bertrand as characteristic of laccase, is not influenced by the presence of manganese salts with or without alkali. But the reaction may be reproduced by the association of ferric salts (ferric chloride) and alkali in suitable proportions. This reaction is affected by very slight variations, certain specimens of guaiacol do not give it; it corresponds to an oxidation by free oxygen and must be rejected as a test for oxydases. The "oxydases reaction" given by milk is no doubt due to the content of alkali and iron. Laccase may be considered to be composed of:—(a), a colloidal substratum coagulable by alcohol; (b), various elements entangled in the coagulum at the time of its formation. These last form two groups: (1), those which are fundamental on account of their giving the typical reactions of laccase; these include manganese and iron salts and alkalis; (2), the accessory elements which have no direct bearing on the oxidations caused by laccase, but which affect its sensitiveness to heat, etc. Very active artificial laccases are obtained when sodium-potassium tartrate is added to the mixtures of manganese salts and alkali, as it prevents their mutual precipitation. For guaiacum and hydroquinone two stages of oxidation exist according to whether the catalyst is used in an acid, or alkaline medium. For the guaiacol reaction of laccase there exists an optimum and a limit of alkalinity; for guaiacol and hydroquinone, on the other hand, the oxidation increases with the concentration of alkali. The author considers laccase to be a fortuitous association of mineral catalysts and it cannot be classed with the digestive or hydrolysing enzymes. The specific action which, together with the sensitiveness to change of temperature, is characteristic of an enzyme is attributed rather to the substratum than to the catalyst itself. Enzymes are extremely sensitive to hydrogen and hydroxyl ions; the colloidal protein element in them seems only to act as an absorbing envelope. Citrates and tartrates owe their catalytic activity towards manganese salts and polyphenols mainly to the hydroxyl ions to which they give rise.

—E. F. A.

Evolution in applied chemistry, (Address). O. N. Witt. Seventh Internat. Congr. Appl. Chem., London, 1909.

THE men who in the past devoted their thought and energy to problems which we now call chemical had to reach their ends with the help of sound empiricism. Though their progress was slow, it was sure, so that to this day we have sometimes occasion to marvel at their successes. More than that, we may safely say that some of our best industrial methods would never have been discovered if we had had chemical theory only to guide us. Science itself stands on an empirical basis—we cannot draw general conclusions unless we have well-established observations to start from.

It is, perhaps, not superfluous to remember these facts at the present time, when the brilliant success of theoretical chemistry is apt to make us forgetful of the services derived from purely empirical methods of research. Empiricism investigates without foregone conclusions, whilst theoretical science verifies logical deductions. Science forces Nature to divulge its secrets; empiricism is quite content to pick up the treasures it may come across in its ramblings through unexplored regions. Nature is still full of unknown treasures; why should we cease to search for them? Why should we expect success only from logical deduction?

One of the best combinations of empiricism and theory is the examination of old empirical industrial processes by the methods and in the light of modern chemical science. A great deal of valuable information has been obtained in this way; much more remains to be discovered. It is this conviction which led me to propose to the last Congress at Rome that a special section should be estab-

lished in these Congresses for the history of Applied Chemistry. The history of chemical science, as it exists now, is almost entirely devoted to theoretical systems and to the life of those who created them. The history of industrial methods is not so complete as one might wish it to be.

As far as the history of our nineteenth century chemical industry goes, the materials for studying it are not wanting. The patent literature of the various countries is in itself an inexhaustible source of information, which can be largely supplemented from text-books and endless files of periodicals. But it is not so if we begin to inquire into the applied chemistry of previous centuries. The mysterious communications of the mediæval alchemists have been frequently examined; but Pliny remains our almost exclusive source of information about the chemical arts of the antique world. Yet these arts were many and highly developed, and Pliny's information was distinctly superficial.

How much more might be gathered about the chemistry of past times, has been shown by the researches of such men as Berthelot and Edmund von Lippman, who combined the accomplishments of distinguished chemists with those of the Orientalist in the study of Arabic and Hebrew authors. Who knows what a host of information may yet be lying dormant in unread Egyptian papyri and palimpsests!

But the sovereign means of discovering these lost secrets is in the careful study and analysis of the products which ancient times have fortunately left us as proofs of their skill and knowledge. How much has been done in that respect by that one great master, Marcelin Berthelot, who found in such work the recreation of the later years of his life! How much more remains still to be done!

Thus we may hope to know at some future time more of the accomplishments of past generations than we do at present. And we may also hope that some of the methods thus rediscovered will awake to fresh life like mummy wheat, which is said to take root and grow if you plant it in fresh soil. Have we not greeted with delight the *terra sigillata* of the Romans, when the process for its manufacture was rediscovered by Fischer, a Bavarian potter, and has not a considerable industry sprung from the resurrected use of lanolin or wool-fat, which was a panacea of the Greeks two thousand years ago?

Yet such discoveries will remain inheritances from the dead, and the cases of their resurrection to life will not be numerous. But we have living empiricism at our doors, which we allow to die and to sink into oblivion without attempting to study it and to learn the lesson it has to teach—a treasure of information of incalculable magnitude, hoarded up in the course of centuries by the skill and patience of countless millions of men, who were and are as keen in the study of nature as they are reluctant to draw general conclusions from their observations.

This great treasure is the industrial experience of the Eastern nations. It is an undoubted fact—and if it were not, a single visit to the South Kensington Museum would prove it—that the people of Persia, India, China, Japan, the inhabitants of Burma, Siam, Cambodja, and the innumerable islands of the Pacific are possessed of methods for the treatment and utilisation of the products of nature which are in many cases equal, if not superior, to our own. These methods must be to a large extent based upon chemical principles. Is it not strange that we know so little about them, and that little generally only indirectly through the accounts of travellers who were no chemists? If all these peculiar methods were fully known and described by persons who have seen them applied and watched their application with the eyes of a chemist, it would certainly be not only of interest, but also of the greatest utility to our own industry. For it is the elucidation of empirical methods which, in the new light that science sheds upon them, leads to new departures and to progress. Who can deny the advantage which the industry of cotton-dyeing and calico-printing derived from the study of the Turkey-red process, which a century ago was bought as an Eastern trade secret by the French Government and generously placed at the disposal of European dyers? Would the making of porcelain have been invented in Europe if the impulse for it had not come

from the East? Is there no connection between the introduction of Chinese porcelain and the invention of Delft, the curious observations of Réaumur on devitrification, and even the work of that great and original genius, Josiah Wedgwood? And would that supreme triumph of the application of pure chemical science to industry, the synthesis of indigo, ever have been accomplished if indigo as a natural dyestuff and its extraordinary method of application by vat-dyeing had not come to us from the East? What a stir has been created even in these very latest days by the extension of this ancient Eastern method of dyeing to other shades than those of indigo!

We live in a period when the intellectual nations of the East wake up from their political sleep of centuries, when they issue from their seclusion and demand their share of Atlantic civilisation. But their awakening means going to sleep for their industrial methods. These methods, ingenious as they undoubtedly are, cannot compete with ours in being applicable on a manufacturing scale. So our processes are transferred to the coasts of the Pacific, and their own methods are abandoned and forgotten. The Eastern industries cannot keep pace with ours, not because they are inferior in their results, but because they toil on foot whilst ours are motoring. In this struggle for existence the fittest means the quickest and the cheapest.

Yet I am certain that many a new and good result might be obtained from the combination of Eastern and Atlantic achievements. Examples of such happy blending are not missing. See what that great and original English inventor, Lord Masham, the very type of an Atlantic genius, has made of the wild silks of India!

It seems to me that these International Congresses ought to make it one of their important duties to watch over the intellectual wealth of the past and to collect it before it disappears for ever. Let the chemists of all countries, who flock together in these gatherings, entrust to their keeping the old indigenous industrial methods of their nations; let the reports of these Congresses, which are distributed over all the world, become a treasure-trove of ancient motives for new development!

If we consider how our present chemical industry has been evolved from empirical processes such as our ancestors practised them, and as they still exist in the countries of the East and even in some parts of Europe, we can easily observe a gradual transformation similar in many respects to the one that living nature had to go through in evolving the present types of plant and animal life. It is here that the parallels between biology and chemistry offer themselves. They are interesting and not useless to consider. It would be strange indeed if we could not gather some acceptable hints from surveying the broad expanse of the human toil and thought of centuries.

Chemistry and the law. Rt. Hon. Lord Alverstone.
Int. Congress of Appl. Chem., 1909.

THE Lord Chief Justice, speaking on the subject of legislating upon and dealing with scientific knowledge, wished to approach the subject from the broadest possible standpoint, and to consider the principles upon which legislation should proceed not in this country alone but in all civilised countries. He did not believe there ought to be different rules in different countries, but as far as possible they ought to see whether in the British Empire, France, Germany, the United States, and other great countries they could not approximate to an international code in connection with the proper protection of inventions. It was from that point of view he wished to consider a step which had recently been taken in Great Britain, a step which to a certain extent followed the example of some other nations with regard to the making it a condition that there should be working in the country in which a patent had been taken out. In his opinion that was a step in the wrong direction which would discourage inventors, and which would make people revert to secret processes, one of the worst forms by which inventions could be developed. Further, it was hard upon the genuine inventor, who was often a very bad man of business

indeed. He had always maintained that view. He would take a kindred illustration—the enactment adopted in England, against his express wish, destroying provisional specifications. Let them protect the inventor as much as they liked, but let them not do anything to destroy public knowledge. Take the case of the scientific men, many of whom had the power of invention and were always thinking of something new, but who often were wholly unfitted to work out the inventions themselves. The real advantage to the public in those circumstances lay in other people taking up the invention and working it. At present the working of a patent was compulsory, and an application might be made to revoke the patent even in the country in which the patentee resided, and that appeared to be driving an idea to an excess. He knew there was a strong impression—he was not the least in favour of it from the Protectionist point of view—that by this means they would then develop the industry of the particular country. It seemed to him that if they were to lay down this test about working they would meet with many difficulties, for the working was different in dealing with chemical products and wholesale manufactures, and between subordinate parts in an old machine and an entirely new machine. They were approaching the subject from the wrong standpoint. He wanted in the first place to protect the inventor so that the product of his invention would be used with advantage to himself and with the largest advantage to the public. If they desired to interfere with the monopoly rights of a patentee, the proper view to take was that there should be freedom of working on a fair licence, if the patentee did not sufficiently work the patent himself. Under those conditions the difficulties about injunctions would to a large extent disappear. If a patentee were a dog-in-the-manger, and would not allow his patent to be worked except on prohibitive terms, by all means have an independent tribunal which should say on what conditions and on what terms the patent ought to be worked. But if they allowed people who really wished to work that patent to do so on fair terms under licence, they need not put on the patentee the burden of working it when he did not wish to do so. There were numbers of illustrations which showed that compulsory working would not be a real remedy for the evil, and would at the same time impose upon many patentees a very great burden. The inventor should be given a fair and not an excessive reward for his invention, and should be freed from those commercial difficulties which had embarrassed so many men. If there were a capitalist, a merchant, or a manufacturer who felt he could make good public use of a patent, let him work it on terms fair to the patentee, but do not let them say that a patent was to be revoked because the patentee was not able to work it. He hoped it was not too late to suggest from an international point of view that patents should be worked by those desirous of working them on fair royalties, paid to the patentee. There ought to be international recognition of invention and discovery. There was no class of invention to which the observations he had made applied more strongly than to the chemical industry. It seemed to him that knowledge was the birthright of no particular nation, but ought to be shared by the whole human race. There ought to be no temptation to bottle up or keep secret the discoveries of scientific men or the results of their labours. The perfect system would be to give every inventor a fair and full—might he say a generous?—reward for his invention, and relieve him in many cases of the anxiety of developing it, so that he might be free to pursue his studies for the benefit of mankind, and to investigate the inexhaustible fields of knowledge yet unexplored.

Fawcett v. Fraser. Decision under Patents and Designs Act, 1907. Times, Aug. 20, 1909.

ON Aug. 19 the Comptroller-General dismissed an application by Thomas C. Fawcett (Limited), of the White House Engineering Works, Leeds, under Section 27 of the above Act, for the revocation of Letters Patent No. 3677 of 1898. The patent in question related to mills for crushing or pulverising rock, quartz, and other materials

and particularly to the class of mills in which the material was crushed between the interior of a revolving ring and the exterior of a roll within the ring.

Mr. Fraser, the proprietor of the patent in question, carried on business in New York, and in February, 1908, in consequence of the passing of the Patents Act, he appointed Mr. Von Gruerber his sole agent in this country for the purpose both of selling the machines and of starting manufacture. Mr. Von Gruerber inserted advertisements in newspapers with a view of obtaining suitable works for the manufacture of the machines in this country. Replies were received from these advertisements and a firm was selected for the purpose of starting manufacture, and was supplied with a model mill. The first machine was started in the same month, and was finished in November; but it was admitted that a considerable number of the parts of this machine were imported from America. A second machine was commenced in November, and this machine was not finished until July, 1909; the explanation given of this delay being that they were waiting for some improved portions of the machine, made under a later patent, which were to come from America in the first instance, and also that there was no immediate demand for the machine. According to the evidence this second machine was made almost entirely of English work, with the exception of the rolls and ring, and Mr. Von Gruerber stated that he was making every effort to get the proper steel for their manufacture in this country. The two machines so manufactured were, it appears, sold in the United Kingdom to British firms. A third machine had now been taken in hand, and it was stated that the rough castings for this had all been made in London, and that it could be completed, if necessary, at any time within a fortnight. It was further shown in evidence that the only manufacture abroad, outside the United States, was in Germany, and that the rate of sale there was an average of two machines per year to the various countries supplied including Germany. The price at which the machine was offered was £520.

Upon these facts the Comptroller-General, following the principles laid down in "Kenrick v. Jefferson" (26 R.P.C., 383), held (1) that there was a manufacture in this country sufficient to meet the present demand for the machines here, and that sufficient reasons had been given for the absence of a more extensive manufacture at present. Foreign countries had not been given any undue preference over this country, nor had there been any conduct on the part of the patentee which would hamper or prevent him carrying out his obligations to carry on an adequate manufacture here. The demand in foreign countries was, as stated above, two machines a year, and if the demand here were to be of similar extent the present manufacture would be amply sufficient to supply this. (2) That, although hitherto the machines had not been made completely in this country, the most distinctive portions—namely, the rolls and the ring—having been supplied in each case from abroad, it was a sufficient answer that these required somewhat special material, and that the patentee was anxious not to prejudice the early sales of the machines by obtaining inferior material. The machine as a whole was now substantially made in this country, and there appeared to be no reason why the ring and the rolls should not also be manufactured here at an early date. (3) That the machines were offered at a reasonable price. In trying these cases of revocation the question was whether or not the price was, broadly speaking, a *bona fide* one, and was not a price adopted for the very purpose of checking and diminishing the demand for the home-manufactured article, and the evidence here was that the machine was offered at the same price both in America and in all foreign countries.

In dismissing the application with costs, the Comptroller-General pointed out that the determination of this case upon the present material and at the present stage did not necessarily decide the issue for all time. If the manufacture of this machine were not adequately carried on in the future, as promised by the patentee, it would be open to the applicants to come again to the Comptroller under the section and ask for revocation, and at a later stage the reasons which called for more lenient treatment now would not, probably, be available.

Trade Report.

The new Patent Treaty between the United States and Germany. Oil, Paint and Drug Rep., Aug. 9, 1909.

THE following is the official text of the new patent treaty just signed by the Secretary of State, and the German Ambassador, in Washington. It was ratified in Washington and Berlin, August 1:—

Article I.

The provisions of the laws applicable, now existing or hereafter to be enacted of either of the contracting parties under which the non-working of the patent, working pattern (Gebrauchsmuster), design or model carries the invalidation or some other restriction of the right, shall only be applied to the patents, working patterns (Gebrauchsmuster), designs or models enjoyed by the citizens of the other contracting party within the limits of the restrictions imposed by the said party upon its own citizens. The working of a patent, working pattern (Gebrauchsmuster), design or model in the territory of one of the contracting parties shall be considered as equivalent to its working in the territory of the other party.

Article II.

This agreement shall take effect from the date of its promulgation and remain in force until the expiration of twelve months following the notice of termination given by one of the contracting parties.

Article III.

The present agreement shall be ratified, and the ratifications shall be exchanged at Washington as soon as possible.

Washington, this 23rd day of February, 1909.

Netherlands Customs Decisions. Bd. of Tr. J., Aug. 5, 1909.

A DECREE of the Dutch Ministry of Finance, dated the 17th June, fixes the tariff classification of the following articles:—

Articles.	Rate of duty.
	dorins, cts.
Fireproof bricks or pots, provided with an opening which can be closed by a fireproof plug, for use in ascertaining the heat of gas ovens, dutiable as "Pottery".	5 % ad val.
Soya oil, a fatty saponifiable oil dutiable, as "Oils not specially mentioned".....	100 kilogs. 0 55
Diacetyldioxime (dimethylglyoxime), a powder prepared from acetic acid, in bottles of 10 gms., without directions as to use....	Free.
Methylacetic acetic methylester, dutiable as "Pyroligneous spirits, &c.".....	litre 1 15
Naphlatan, a medicine composed of mineral oil and a little soap, in tins of 50, 100, 200, 400 or 800 gms., provided with directions for use, dutiable as "Small wares"....	5 % ad val.
Coloured printing ink, and mixing inks for printing inks, for use in commercial printing works, in any packing.....	Free.
Lysol, a disinfectant, dutiable as "Soap, other, soft".....	100 kilogs. 1 00
Asphalt tar compound, a paint, consisting of a solution of asphalt in heavy coal tar oil, dutiable as "Paints ground in oil".....	5 % ad val.

Special beer priming.—A liquid to be added to extracts in breweries, consisting of a semi-inverted sugar syrup with a purity factor of 92, is subject to the excise duty on sugar.

Russian trade possibilities. For. Off. Ann. Series No. 4295. [T.R.]

THE following information is from the report by the British Vice-Consul at Nicolaieff:

Stationary requisites.—Foolscap paper is exclusively of Russian make. Letter paper comes mostly from

Germany, though a little of the best quality is British. Ink comes chiefly from Germany. There is a little of Russian production. A market might be found for British ink if expense were saved by direct importation. India-rubber bands are principally of Austro-Hungarian make. Copying paper is imported from Germany. British manufacturers might compete if they arranged to sell direct.

Colours, paints, varnishes, and wallpaper.—There is a large sale of zinc white. It is at present of Russian production, but the United Kingdom might compete if direct sales were made. The better qualities of ochre, bought through Odessa, come from Marseilles: the average retail price is 1½d. to 1¾d., per lb., or 14s. to 16s. 4d. per cwt. The cheaper kinds, for sale to the peasants, come from the Caucasus and are sold at ¾d. per lb. There is a certain import of special sorts of enamel paints, but the greater part is made in the country. There is a possible market for imported varnishes of the best qualities. A market might so be found for British wallpapers of the best qualities.

Drugs and perfumery.—Drugs and perfumery are imported, but Russian perfumery commands the largest sale. A direct trade might increase the import.

The following information is from the report of H.M. Consul-General at Odessa:

Vegetable butter.—Vegetable butter is daily becoming more and more popular. The two factories at Odessa and the one at Kieff which recently started its manufacture from copra cannot meet the demand. The present wholesale price is £2 8s. per cwt. The import duty on copra is 1s. 7½d. per cwt.; the import duty on vegetable butter is 10s. 9d. per cwt.

Toilet soaps and scents.—British toilet soap is little imported into South Russia. The French and the home-made articles are generally purchased. This is partly on account of their gay wrappers designed to recommend the articles to purchasers of small presents—a purpose for which they are often used in Russia.

Scents are largely imported from Germany and France.

Paper.—It might be profitable for paper manufacturers to examine the material sold in Russia. Strong paper of long fibre pulp and strong brown paper for wrappers are not to be had.

Roumanian chemical industry, 1908. Chem. Ind., 1909, 32, 403—404.

The chemical industry comprises 51 industrial establishments, including 23 petroleum refineries, 13 stearine and soap works, 6 vegetable oil works, 4 producing sulphuric acid and artificial fertilisers, 3 for the manufacture of varnishes and paints, and 2 for the production of wax candles. The hands employed number 2264; the invested capital amounts to 16.4 million francs, the working capital 10 million francs, and the annual value of the output is 25.6 million francs. The soap and stearine candle industry produces enough to supply the home market, except in the case of fine scented soap the manufacture of which has recently been started; and a small quantity of candles imported from Austria; at the raw material, stearine, has to be imported from Holland, France and Belgium, tallow from Hungary. Candle wicks from Bohemia, France and Italy. Pressed tallow comes from America; coconut oil and resins via Trieste and Hamburg; caustic soda from Belgium; essential oils, essences and glycerine from Germany and France. Paraffin wax and candles are made in a newly erected works at Campina. The largest of the vegetable oil works, at Bukarest, is well equipped, and has silo accommodation for 200 wagon loads of oil seeds. The annual output of oils is about 1200 tons and 200—300 wagon loads of oil cake are produced. The linseed oil produced is worked up into varnish and paint; and soap is made from the crushing waste. Salt, the most important mineral product of the country, is a State monopoly. The annual output is 95,000 tons, of which about 30,000 tons are exported to adjoining countries and Egypt. The petroleum industry is flourish-

ing, though the output has not increased, and large quantities of crude oil have to be imported from Galicia. Great expectations, however, are formed as to the new oil districts of Pacureti and Tintea. The exports of oil via Konstantza amounted to about 363,000 tons, of which France took nearly 124,000 tons, England 96,000 tons, India 52,000 tons, Egypt 44,000 tons, Italy 20,000 tons, Belgium 17,700 tons, Germany 5,200 tons and Austria-Hungary 3,300 tons. The price of "benzine" (sp. gr. 0.710—0.715) receded from 21 francs f.o.b. Konstantza to 17 francs, but improved on the formation of a syndicate. The exports to England amounted to 20,800 tons, 67,400 tons being consigned to France and 4290 tons to Italy. Refined oil was exported to the extent of 5270 tons to Germany, 35,880 tons to England, 3306 tons to Austria-Hungary, 17,160 tons to Belgium, 43,830 tons to Egypt, 805 tons to France, 51,849 tons to India and 15,800 tons to Italy. Distilled petroleum was exported to France alone, where the duty is less than on refined, the quantity amounting to 55,670 tons. Owing to the growing inland consumption of residuum for fuel purposes, only 7800 tons were exported. In the East, Roumanian oil has to meet keen competition on the part of Russia in case oil, of which 1,200,000 cans (17,400 tons) were exported.—C. S.

Hungarian chemical industry: Present condition and prospects of the —. G. Bokor. Seventh Int. Congr. Appl. Chem., London, 1909. Chem. Ind., 1909, 32, 403.

The large works producing acids and alkalis are more than capable of supplying the needs of the home market. Sulphuric acid manufacturers have an abundant supply of raw material in the rich pyrites of Upper Hungary and Siebenbürgen. The output of ammonia-soda exceeds the home requirements; and the manufacture of caustic soda is shortly to be commenced. The bone glue industry produces for export; and large quantities of wood spirit and acetone, from wood distillation, are consigned to Austria, Switzerland and England. Four large works produce tannin, which is also exported; and the starch industry exports products to the value of about £208,000 (5 million kronen) per annum. For the last nine years, the petroleum refineries have dealt almost exclusively with Galician crude oil, and contribute largely to the export trade of the country. The future prospects are favourable for the soap, vegetable oils, pharmaceutical products and colour industries, though these need to be further developed. It is doubtful whether the coal-tar dyestuff industry is calculated to flourish in Hungary; but there is a possibility of the lucrative production of mineral pigments. The law relating to the encouragement of industries has largely favoured the construction of new chemical works; but improved chemical training and revision of the patent law are needed.—C. S.

Books Received.

Treasury Department. Public Health and Marine—Hospital Service of the United States, Hygienic Laboratory. Bulletin No. 49. March, 1909. DIGEST OF COMMENTS ON THE PHARMACOPOEIA OF THE UNITED STATES OF AMERICA. [8th Decennial Edition.] For the period ending December 31, 1905. By MURRAY GALT MOTTER and MARTIN J. WILBERT. Government Printing Office, Washington. 1909.

Two volume, containing 295 pages of subject matter, classified as follows:—I. Preface. II. List of literature reviewed—Journals, and pharmacopoeias. III. General comments: (i.), General principles followed in revising the pharmacopoeia. (ii.), Scope. (iii.), Analytical data. (iv.), Biological remedies. (v.), Vegetable drugs. (vi.), Pharmaceutical preparations. IV. International standards. (i.), International conference for the unification of pharmacopoeial formulae for patent medicaments (Brussels Conference). (ii.), Foreign pharmacopoeias. (iii.), Pharmacopoeial history. V. Comments on official articles.

EINRICHTUNG VON LABORATORIEN UND ALLGEMEINE OPERATIONEN. Von Dr. VICTOR SANTER. Wilhelm Knapp's Verlag, Halle a.S. 1909. Price M.2.70.

8vo volume, containing 65 pages of subject matter, with 53 illustrations. The subject matter is arranged under the following class-headings:—I. Organisation of the analytical laboratory. Capacity and function of the analyst outside the laboratory. II. Position and general arrangement of the laboratory. III. General operations: (a), Sampling and reducing to physical condition for analysis (pulverisation, &c.). (b), Balance and weighing. (c), Indirect weighing. (d), Estimation of quantities by measuring. (e), Solids. (f), Gases. (g), Evaporation. (h), Filtering, washing, and precipitation. (i), Drying and igniting. IV. Special methods of analysis usual in technology: (a), Volumetric analysis. (b), Electrolysis. (c), Colorimetry.

DIE ELEKTROCHEMISCHEN VERFAHREN DER CHEMISCHEN GROSS-INDUSTRIE. IHRE PRINZIPIEN UND IHRE AUSFÜHRUNG. Von Dr. JEAN BILLITER. I. Band. Elektrometallurgie wässriger Lösungen. Wilhelm Knapp's Verlag, Halle a.S. 1909. Price M.12.70.

8vo volume, containing 284 pages of subject matter with 117 illustrations and numerous tables. The subject matter is classified and arranged in the following chapters: Introduction. Theory of ions. Faraday's law. Law of dilutions, &c. Polarisation, &c. CHAPTER I. COPPER.—(a), Its electrolytic refining. (b), Electrolytic production of copper from copper ores. (Processes of Marchese, Höpfner, Siemens and Halske). (c), Cathodic separation, and electrolytic preparation of finished articles. II. SILVER.—(a), Electrolytic refinement. (b), Electrolytic preparation from alloys. III. GOLD.—(a), Electrolytic gold refining. Electrolysis with crude gold anodes. (b), Electrolytic gold recovery from ores. IV. LEAD.—(a), Electrolytic lead refining. (b), Lead recovery from ores. V. ZINC.—(a), Electrolytic zinc extraction. (b), Zinc recovery from ores. (c), Processes in the electrolysis of zinc chloride and zinc sulphate solution. Zinc from zinc sulphate solutions (Process: Siemens and Halske). Zinc from zinc chloride solutions (Process: Höpfner). VI. The detinning of tinplate. VII. NICKEL. Its electrometallurgy. VIII. (i.), Refining of bismuth and cadmium. Extraction of antimony and mercury. (ii.), Electrolysis with soluble anodes, in the recovery of metallic compounds (Iron—lead colours).

CIMICA GENERALE E APPLICATA ALL'INDUSTRIA. VOLUME II.—CHIMICA ORGANICA. Del Dott. E. MOLINARI. U. Hoepli, Milano, 1908 and 1909. Price, Lira 18.

THE work is issued in two 8vo volumes containing 956 pages of subject matter, with 486 illustrations, and an alphabetical index. The subject matter of the whole work is classified as follows:—PART I.—I. General part: Purification of organic substances; analysis; calculation of formulae; determination of molecular weights by chemical methods; polymerism; valency of carbon, constitutional formulae, isomerism; metamerism, pseudoisomerism, tautomerism, desmotropy; stereoisomerism; homology and isology, classification of organic substances; official nomenclature; relations between physical properties and chemical composition and constitution. II. Special part: Derivatives of methane. (A.) Hydrocarbons. (B.) Halogen derivatives of hydrocarbons. (C.) Alcohols. (D.) Derivatives of alcohols. (E.) Acids. PART II.—(F.) Derivatives of acids. (G.) Polyvalent aldehydic and ketonic alcohols. III. Special part: Cyclic compounds. (A.) Isocyclic compounds: Aromatic hydrocarbons. (B.) Halogen substitution derivatives of benzene. (C.) Sulphonic acids. (D.) Phenols. (E.) Quinones. (F.) Nitro-derivatives. (G.) Amino-derivatives. (H.) Nitro-, amino-, and thio-phenols. (I.) Azo-, diazo-, and diazo-amino-compounds and hydrazines. (L.) Aromatic alcohols, aldehydes, and ketones. (M.) Hydroxy-alcohols and aldehydes, and ketonic alcohols. (N.) Aromatic acids. (O.) Hydrogenised benzene derivatives. (P.) Condensed benzene nuclei. (Q.) Heterocyclic compounds. (R.) Colouring matters. (S.) Textile fibres. (T.) Protein substances, glucosides, and substances of uncertain or unknown constitution. Appendix.

PATENT OFFICE LIBRARY: SUBJECT LISTS, NEW SERIES B.F.-BL. SUBJECT LIST OF WORKS ON THE LAWS OF INDUSTRIAL PROPERTY (PATENTS, DESIGNS, AND TRADE MARKS) AND COPYRIGHT IN THE LIBRARY OF THE PATENT OFFICE. Love and Malcolmson, Ltd., 4 and 5, Dane Street, W.C. Patent Office, 25, Southampton Buildings, London, W.C. 1909. Price 6d.

POCKET-BOOK size, 80 pp., and a key to the classification of Headings (B.F. to B.G.). This volume superseded *Patent Office Library Series*, No. 3, published in 1900.

SOME ELECTRO-CHEMICAL CENTRES. A report to the Electors of the Gartside Scholarships. By J. N. PRING, M.Sc. (Gartside scholar), Manchester. At the University Press, 1908. Price 1s. 6d.

8vo volume, containing 136 pages of subject matter and an alphabetical index. The report is based principally on information acquired during visits to several countries, on "the continent of Europe and to the United States and Canada, including British Columbia, during the years 1907 and 1908." The subject matter is classified as follows:—I. Cost of power production. II. Niagara Falls. III. The copper refineries of New Jersey. IV. Canadian water powers and electro-chemical centres. V. Electric smelting of iron ores and steel production. VI. Ozone and water purification. VII. Gold and silver refining. VIII. Electrical manufacture of carbon bisulphide. IX. Electro-chemical industries in the Alps, France, and Belgium. X. Electrical fixation of atmospheric nitrogen. XI. Power centres and electro-chemical works in Great Britain.

DYEING IN GERMANY AND AMERICA, with a Chapter on Colour Production. A Report to the Electors of the Gartside Scholarships on the results of a tour in Germany and the United States in 1905-6. By SYDNEY H. HIGGINS, M.Sc., Gartside Scholar. University Press, Manchester, 1907. Price 1s. Sherratt and Hughes, Manchester: 34, Cross Street; London: 33, Soho Square, W.

8vo volume, containing 105 pages of subject matter, and the alphabetical index. The subject matter is classified and arranged under the following chapter heads:—I. General. Distribution of the industry in America and Germany. Development of the art of dyeing. Influence of chemistry. Opposition to progress. Hank dyeing and washing. Cloth dyeing. II. Cop dyeing. III. Sulphur colours, and indigo. IV. Mercerising. V. Bleaching. VI. The industry in the United States. VII. Lowell, Lawrence, and Fall River, Mass. VIII. Conditions of the industry. IX. Efficiency in the industry. X. Colour production.

BAMBOO FOR PAPERMAKING. By R. W. SINDALL. Marchant, Singer and Co., London. 1909. Price 2s.

8vo volume, 60 pp., printed on paper produced from the bamboo, and describing the possibilities of bamboo for paper-making, the habit and growth of the plant, its flowering and propagation, with information as to price and supply; to which are added particulars of experiments on paper manufacture therefrom, and the necessary plant and mill equipment. The whole is the outcome of a visit made in 1905 to Burma by the author, at the request of the Indian Government, which is prepared to offer special terms to those who will undertake the manufacture. (See also this J., 1907, 1157.)

Patent List.

I.—PLANT, APPARATUS, AND MACHINERY. APPLICATIONS.

17,903. Epstein. See under VII.

17,914. Goldstein. Manufacture of highly absorbent carbonaceous material. Aug. 3.*

18,013. Stuble and White. Apparatus for separating dust from air or gases.* Aug. 4.

18,194. Newton (F. Bayer und Co.). Steam traps. Aug. 6.

18,397. Crighton, and Klein Engineering Co. Apparatus for cooling liquids. Aug. 10.

18,452. Bary. *See under X.*

COMPLETE SPECIFICATIONS ACCEPTED.

11,557 (1908). Allan and Richmond. Boilers for melting bitumen, pitch, marine glue, and grease. [Post dated Nov. 30, 1908.] Aug. 11.

16,817 (1908). Faller. Evaporating boilers for use in crystallising liquids. Aug. 18.

17,500 (1908). Joy. Apparatus for raising and forcing water and other liquids and semi-liquids. [Cognate Appl., 3407 of 1909.] Aug. 11.

22,184 (1908). Jeffcock and Yardley. Separator for treating steam and other gaseous and liquid bodies. [Cog. Appl., 9230 of 1909.] Aug. 11.

3623 (1909). Vautin. Generation of steam from the heat contained in slags. Aug. 18.

5365 (1909). Dehne. Milk separators and other centrifugal machines. Aug. 18.

8164 (1909). Wilkinson, Heywood, and Clark, Ltd., and Gordon. Dipping tanks. Aug. 18.

H.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

17,889. Schuster. Regenerative coke ovens. Aug. 3.

18,123. Tigges. Gas producers. [Ger. Appl., Aug. 6, 1908.]* Aug. 5.

18,413. Jones. Quenching coke. Aug. 10.

18,593. Izod. Manufacture of ozonised or oxygenised carburetted vapour or gas. Aug. 12.

18,652. Crombie. Treating fuel and collecting the by-products. Aug. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

16,157 (1908). Hiller, and National Boiler and General Insurance Co. Gas-testing burner for producer gas plants. Aug. 11.

16,448 (1908). Bethge. Combustible mixtures for producing actinic light. Aug. 18.

16,610 (1908). Versen. Gas producers. [Rights under Section 91 not granted.] Aug. 18.

16,762 (1908). Ziegler and others. *See under V.*

21,249 (1908). Seymour. Horizontal regenerative coke oven. Aug. 18.

11,890 (1909). Crossley and Rigby. Gas producer plant primarily for recovering ammonia. Aug. 11.

III.—DESTRUCTIVE DISTILLATION. TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

18,076. Hercog and Linke. Process for producing condensed petroleum. Aug. 5.

18,120. Weiser. Process for separating paraffin from paraffin butter and apparatus therefor.* Aug. 5.

18,334. Noad. Distilling shale and other bitumens. Aug. 9.

18,604. Smith, Mitchell, and Askham. Tables or slabs for dry-cleaning processes with volatile liquids. Aug. 12.

18,605. Smith, Mitchell, and Askham. Recovering volatile solvents. Aug. 12.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

18,117. Imray (Meister, Lucius, und Brüning). Manufacture of new vat dyestuffs. Aug. 5.

18,461. Wetter (Chem. Fabr. Grünau, Landshoff, und Meyer A.-G.). Manufacture of new alizarin preparations suitable for dyeing and printing.* Aug. 10.

18,477. Claus and Co., and Claus. Manufacture of a thiazine dyestuff. Aug. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

12,167 (1908). Johnson. (Badische Anilin und Soda Fabrik). Manufacture of colouring matters of the anthracene series. Aug. 11.

339 (1909). Johnson (Badische Anilin und Soda Fabrik). Manufacture of colouring matters of the anthracene series. Aug. 18.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

17,967. Dykes and Dykes. Dyeing, bleaching, and mercerising machine. Aug. 4.

18,016. Nowicki. Hygroscopic substitute for cotton-wool.* Aug. 4.

18,086. Loewe. Process for the manufacture of artificial silk or for coating and glossing textiles and apparatus therefor. [Fr. Appl., Sept. 18, 1908.]* Aug. 5.

18,391. Wittington. Printing calico, paper, and yarn. Aug. 10.

18,448. Resch and Gutsch. Apparatus for use in chemical cleaning. [Ger. Appl., Aug. 31, 1908.]* Aug. 10.

18,461. Wetter. *See under IV.*

18,481. Daniels. Apparatus for dyeing wool. Aug. 11.

18,649. Scholefield and Downham. Dyeing and bleaching fibres.* Aug. 13.

18,701. Johnson (Badische Anilin und Soda Fabrik). Production of shades on vegetable fibre. Aug. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

16,557 (1908). Crombie. Apparatus for making fibres from solutions. Aug. 11.

16,762 (1908). Ziegler, and Oberbayerische Kokswerke und Fabrik Chemischer Produkte A.-G. Method of depriving peat and like vegetable fibrous materials of superfluous moisture. Aug. 11.

2024 (1909). Koreinek. Production of samples representing printed textile fabrics. Aug. 11.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

17,903. Epstein. Treatment of air for different purposes. Aug. 3.

17,951. Johnson (Badische Anilin und Soda Fabrik). Manufacture of ammonia and apparatus for use therein. Aug. 3.

17,955. Rowley. Process for the conversion of crude phosphatic rock into water soluble phosphate. Aug. 3.

18,203. Bender. Process for production of oxides of nitrogen.* Aug. 6.

18,206. Palmer and Stead. Apparatus for use in deodorising carbon dioxide. Aug. 6.

18,286. Vender. *See under XXI.*

18,329. Wolff. Obtaining tin tetrafluoride from tin scrap. Aug. 9.

18,433. Levi. Electrochemical production of phosphatic fertilisers.* Aug. 10.

18,661. Robinson (Morton and Co.). Apparatus for purifying air. Aug. 13.

18,700. Johnson (Badische Anilin und Soda Fabrik). Manufacture of ammonia. Aug. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

14,349 (1908). Brotherton and Wyld. Saturator for the manufacture of ammonium sulphate. Aug. 18.

16,156 (1908). Gartenmeister. Process for purifying chlorates. Aug. 11.

16,542 (1908). Otto. Production of ozone. [Date Appl. for, Aug. 10, 1907.] Aug. 11.

17,356 (1908). Peniakoff. Process for rendering silica contained in sodium aluminate insoluble for the purpose of obtaining silica-free alumina. Aug. 11.

20,366 (1908). Ellis (Chemische Werke vorm. Dr. H. Byk). Manufacture of nitric acid. Aug. 18.

25,965 (1908). Meyer. Process of manufacturing sulphide of zinc. [Date Appl. for, Dec. 3, 1907.] Aug. 11.

11,890 (1909). Crossley and Rigby. *See under II.*

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

18,118. Sauvageon. Electric furnaces for the continuous manufacture of glass. Aug. 5.

18,322. Quertinmont. Apparatus for making sheet or plate glass.* Aug. 9.

18,323. Quertinmont. Manufacture of glass.* Aug. 9.

18,713. Voelker. Forming bodies from semi-liquid quartz.* Aug. 14.

COMPLETE SPECIFICATION ACCEPTED.

9853 (1909). Sievert. Glass making apparatus. Aug. 11.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

18,088. Rhodin. Production of hydraulic cement from blast furnace slag. Aug. 5.

18,230. Wilson. Manufacture of cement, plaster, and concrete. Aug. 7.

18,293. Wilson. Manufacture of cement, plaster, and concrete. Aug. 9.

18,357. Pink. Making artificial marble and floor and wall coverings. Aug. 9.

18,670. Associated Portland Cement Manufacturers, Bamber, and Baxter. Drying slurry. Aug. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

23,988 (1908). Rhodin. Manufacture of slag cement. Aug. 18.

2534 (1909). Mueller. Process of impregnating wood. [Date Appl. for, Feb. 15, 1908.] Aug. 11.

2599 (1909). F. L. Smith and Co. Treatment of stony or earthy materials for the manufacture of cement. [Date Appl. for, Feb. 27, 1908.] Aug. 11.

5908 (1909). Chisholm. Method of treating wood. Aug. 11.

7530 (1909). Owen. Preparing asbestos fibre for insulating purposes. Aug. 11.

X.—METALS AND METALLURGY.

APPLICATIONS.

17,911. Monge. Manufacture of metallised articles.* Aug. 3.

18,176 and 18,178. Martin. Process for separation of complex ores. [Pat. of Addn. to No. 4531 of 1909.] Aug. 6.

18,198. Soc. Anon. "Le Ferro-Nickel." Light aluminium alloys. [Fr. Appl., Aug. 29, 1908.]* Aug. 6.

18,239. Beauchamp. Process for extraction of zinc. [Addition to 17,330 of 1909.] Aug. 7.

18,349. Hargreaves. Production of iron or steel direct from the ore.* Aug. 9.

18,451. Bary. Process and apparatus for casting metals. Aug. 10.

18,452. Bary. Furnaces. Aug. 10.

18,610. Hoff. Process and apparatus for heating, melting, refining, and decomposing metals.* Aug. 12.

18,731. Hoy and Rogerson. Welding steel or iron and flux therefor. Aug. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

16,552 (1908). Thompson (Wm. Sauntry Metals Co.). Process for the treatment of steel and iron. Aug. 11.

16,806 (1908). Marks (Gio Ansaldo, Armstrong, and Co.). Manufacture of cemented armour plates of steel for ships. Aug. 11.

16,820 (1908). Clark. Coating of iron or steel with copper, or other metal, such as silver or gold, which alloys with copper. Aug. 18.

22,092 (1908). Richford. Process of producing lead or other metal in thread-like or finely divided form. Aug. 11.

23,779 (1908). Stalder, Scholl-Scholl, and Dubach. Process for soldering aluminium. Aug. 18.

3623 (1909). Vautin. *See under I.*

8272 (1909). Jeffery. Flux for use in soldering aluminium with ordinary tin and lead solder and copper bit. Aug. 11.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

18,118. Sauvageon. *See under VIII.*

18,433. Levi. *See under VII.*

18,590. Marino. Preserving or protecting from peroxidation the lead supports of the positive electrodes of storage batteries.* Aug. 12.

COMPLETE SPECIFICATIONS ACCEPTED.

24,355 and 24,356 (1908). Schauli. Depolarisers for electric batteries. [Date Appl. for, July 9, 1908.] Aug. 18.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATIONS.

18,236. Tuckfield and Garland. Bleaching and purifying fats and oils. Aug. 7.

18,588. Nicholson. *See under XIV.*

COMPLETE SPECIFICATIONS ACCEPTED.

26,133 (1908). Landemann (Geh. Korting A.-G.). Manufacture of pulverised soap. [Request under Section 19 not granted.] Aug. 18.

1550 (1909). Justice (Mills and Battle). Extraction of oil from materials such as seed. Aug. 11.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES: INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

COMPLETE SPECIFICATIONS ACCEPTED.

16,476 (1908). Williamson (Taylor). Preservative antifouling and anticorrosive paint. Aug. 11.

17,557 (1908). Fraser. Paint or composition for colouring articles and surfaces. Aug. 18.

26,521 (1908). Langbein-Pfahhauser Werke A.-G. Process for rustproof coating of iron and steel. [Date appl. or, Dec. 21, 1907.] Aug. 18.

(B.)—RESINS, VARNISHES.

APPLICATION.

18,149. Morris. Preservative materials for leather. Aug. 6.

(C.)—INDIA-RUBBER.

APPLICATIONS.

18,493. Newton (F. Bayer und Co.). Insulation of metallic threads or wires. [Under Rule 13, May 13, 1909.] Aug. 6.

18,503. Gallagher and Rendle. *See under XIV.*

18,678. Melsom. Treatment and utilisation of waste rubber, vulcanite, and ebonite. Aug. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

18,929 (1908). Upson (Christy). Implement for tapping *Funtumia Elastica* and other rubber producing trees. Aug. 11.

23,814 (1908). Asimont and Galley. Instrument for use in the tapping of rubber trees. Aug. 11.

XIV.—TANNING, LEATHER, GLUE, SIZE, &c.

APPLICATIONS.

18,149. Morris. *See under XIII B.*

18,411. Cave-Browne-Cave. Treatment of leather, fur, and skins. Aug. 10.

18,468. Meiro. Extraction of grease and glue from bones. Aug. 10.

18,503. Gallagher and Rendle. Method of combining leather and rubber.* Aug. 11.

18,588. Nicholson. Process and apparatus for extracting fat from bones. Aug. 12.

COMPLETE SPECIFICATION ACCEPTED.

9383 (1909). Buffum and Carter. Waterproof leather-board and process of preparing it. [Pat. of Addn. to No. 28,219, 1908.] Aug. 11.

XV.—MANURES, &c.

APPLICATIONS.

17,937. Patent-Press-Kartoffel-Industrie Hermann Gumpel. Process for treating raw potatoes so as to obtain a durable product for agricultural and industrial purposes.* [Ger. Appl., 7th May, 1909.] Aug. 3.

17,955. Rowley. *See under VII.*

18,433. Levi. *See under VII.*

XVI.—SUGAR, STARCH, GUM, &c.

COMPLETE SPECIFICATION ACCEPTED.

26,619 (1908). Cie. Industrielle des Alcools de l'Ardeche. Apparatus for converting wood into fermentable sugars and other products. [Date Appl. for, June 9th, 1908.] Aug. 18.

XVII.—BREWING, WINES, SPIRITS, &c.

APPLICATIONS.

18,028. Compagnie Industrielle des Alcools de l'Ardeche. Separating apparatus for use in the manufacture of alcohol.* [French Appl., Oct. 16, 1908.] Aug. 4.

18,216 and 18,217. Kuhn. Manufacture of fermented beverages. [Addition to No. 4622 of 1908.] Aug. 6.

18,218 and 18,219. Kuhn. Manufacture of beverages. Aug. 6.

18,530. Faulkner and Duncan. Manufacture of malt preparations. Aug. 11.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

17,992. Loring. Art of ageing and conditioning flour. [Pat. of Addn. to No. 12,781 of 1908.] Aug. 4.

18,201. Buer. Process for the production of butter flavour.* Aug. 6.

18,337. Collett and Eckardt. Process for production of dietetic cocoa.* [Norwegian Appl., Aug. 10, 1908.] Aug. 9.

COMPLETE SPECIFICATION ACCEPTED.

22,221 (1908). Goetz and Jones. Processes of pasteurisation. Aug. 18.

(B.)—SANITATION; WATER PURIFICATION.

APPLICATION.

18,429. Welcome. Deodorising and drying nighsoil.* Aug. 10.

COMPLETE SPECIFICATIONS ACCEPTED.

16,397 (1908). Grossmann. Treatment of sewage-sludge. Aug. 11.

17,244 (1908). Liversedge. Process for purification of water or sewage. Aug. 18.

—PLANT, APPARATUS, AND MACHINERY.

Compressors for gases. (Frankfort Internat. Aeronaut. Exhibition.) Times Eng. Suppl., Aug. 25, 1909, 18.

THE great heat developed by the compression of hydrogen to 200 atmospheres has led to the manufacture of high pressure compressors which do the work in three stages. The compressors contain three high-pressure cylinders arranged in tandem. In the first cylinder compression takes place to 6 atmospheres, in the second to 36 atmospheres, and in the third to about 200 atmospheres. These compressors are made for air, hydrogen, oxygen, nitrogen, carbonic acid, or acetylene up to 1000 atmospheres pressure, but for more than 250–300 atmospheres four stages are employed, two twin-cylinders being used. All valves are arranged in a vertical plane with the cylinders. These machines take up very little space, are simple, and every part is easily accessible and transportable. They seem to require very little attention, and are used in chemical factories as well as in connection with military air-ships.

PATENTS.

Cooling and refrigeration of liquids or fluids. W. Hewitt, London. Eng. Pat. 20,381, Sept. 28, 1908.

THE apparatus consists of a hollow hub, 1, divided into two chambers, *a*, *a*¹, by the partition, 2. The hub is provided with projecting hollow blades or wings, 3, also divided by partitions, 7, into two chambers which communicate respectively with the chambers, *a*, *a*¹, by the ports or openings, 4. The apparatus is provided with a concentric hollow trunnion, 8, within which is a tube, 261, communicating at one end with the compartment, *a*, of the chamber, 1, and at the other with the chamber, 10, which forms the outlet for the liquid. The hollow shaft, 8, is secured upon it, a driving pulley or chain wheel, 24, 25, 26, indicate the admission- and exit-orifices respectively, of the stationary chambers, 27 and 10. The liquid to be cooled is forced into the stationary chamber, 25, passes along the outer hollow shaft, 8, into the chamber, *a*¹, and thence through 4, 6, 5, and into the chamber, *a*, from which it is discharged through the central hollow trunnion, 261, into the chamber, 10. The liquid partakes of the revolution of the hub and wings and is cooled by the air. If desired the liquid may be circulated through the hub and wings by a centrifugal pump carried on the hollow trunnion.—W. H. C.

Separating solid matters from air; Centrifugal apparatus for —. A. Lebrasseur, Paris. Assignor to The Sturtevant Engineering Co., Ltd., London, England. U.S. Pat. 928,673, July 20, 1909.

A CONICAL chamber has an inlet pipe fixed tangentially and a conical exit pipe fixed centrally at its top. The annular space between the exit pipe and the conical chamber contains a continuous spiral vane forming a spiral passage of increasing cross-sectional area for the entering air. Above the opening of the exit pipe a flat disc is carried on short columns to spread the air leaving the apparatus.—J. W. H.

Packing and process of making same. T. Murphy, Cleveland, Ohio. U.S. Pat. 928,875, July 20, 1909.

LEAD and Babbit metal are melted, and a mixture of graphite and mica stirred in until the whole is in a granular state. Asbestos fibre and oil are then incorporated with the mixture until a compact pliable mass is obtained, forming the packing in question.—J. W. H.

Centrifugal machine for separating heavy from light materials. Jahn-Kommanditgesellschaft, Maschinenbau-Anstalt, Eisengiesserei und Kesselschmiede. Fr. Pat. 399,829, Feb. 22, 1909.

A CONICAL drum closed below and open above and provided with a helical blade on its interior surface is mounted on an axis so that it can be rotated. The materials to be separated are fed into the open top of the drum from which the heavier particles are also discharged. The lighter particles are discharged through openings in the bottom of the drum arranged at a greater distance from the axis than the semi-diameter of the upper opening of the drum.—W. H. C.

Filtering liquids; Process for — and apparatus therefor. J. Resines, Matanzas, Cuba. Eng. Pat. 23,720, Nov. 5, 1908.

SEE Fr. Pat. 396,173 of 1908; this J., 1909, 591. Reference is directed, under Sect. 7, Sub-Sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 3064 of 1892, 7491 of 1896, and 20,850 of 1899.—T. F. B.

II.—FUEL, GAS, AND LIGHT.

PATENTS.

Fuel for internal combustion engines. G. B. Selden, Rochester, N.Y. U.S. Pat. 928,803, July 20, 1909. (Renewed May 13, 1909.)

TO a suitable liquid hydrocarbon, a pierate of a suitable hydrocarbon, such as naphthalene, is added. A peroxide such as hydrogen peroxide may be a further addition.—J. W. H.

Tar and liquid hydrocarbons; New method of utilising — for heating. E. Hovine. Fr. Pat. 399,274, Feb. 9, 1909.

THE tar and liquid hydrocarbons are gasified in the upper part of a gas-producer charged with coke, this producer being worked with a blast of air sufficient only to maintain the necessary temperature. The gases formed from the tar, &c., mixed with a certain quantity of producer gas, are led away and burned in a furnace. The upper part of the producer is provided with one or more inclined surfaces which are maintained at red heat by the fire in the producer, and the tar is run on to these surfaces in thin streams. The coke which is formed on these inclined surfaces is raked from time to time into the producer fire and serves to maintain the level of the fuel.—A. T. L.

Hot air furnace. J. M. Keller, Youngstown, Ohio. U.S., Pat. 928,259, July 20, 1909.

THE furnace has a circular grate with a central hole. A gas producer shell having an opening at its side for feeding the fuel and an opening in its base, is supported at a short distance above the grate. A perforated cylinder with a perforated conical top and carried by a lever, closes the lower opening in the gas producer shell, and passes through the hole in the circular grate. By this means the fuel may be made to fall on the circular grate, while the gases generated, can pass through the perforations. The whole is enclosed in a shell over which the air to be heated, passes, provision being made for the removal of ash, &c.—J. W. H.

Gas-furnace. J. Bueh, Dessau, Germany. U.S. Pat. 928,494, July 20, 1909.

PARALLEL streams of gas and air, are delivered into a combustion chamber having projections from its roof, and movable baffle plates on its hearth, to modify the course of the burning gases.—J. W. H.

Gas producers. A. B. Duff, Pittsburg, U.S.A., and The Gas Power and By-Products Co., Glasgow. Eng. Pat. 7780, April 1, 1909.

THE patent relates to producers of the type having a rotatable water-sealed top-plate carrying adjustable water-cooled pokers for stirring the fuel by the rotation of the top-plate. The top-plate is carried by a vertical flange extending downwards from its periphery and resting on rollers in an annular water seal, and it is guided by rollers on vertical spindles, which bear against its periphery. The pokers are pivoted in the top-plate about the middle of their length, and their upper ends engage nuts working on horizontal screwed rods, so that the lower ends of the pokers can be given a lateral movement by turning these rods. The top-plate may be water-cooled, if desired.—A. T. L.

Gas producer plants primarily designed for the recovery of ammonia. W. J. Crossley and T. Rigby, Manchester. Eng. Pat. 11,890 of 1909; date of application, Aug. 27, 1908.

IN gas producer plants of the Mond type, or of the type described in Eng. Pat. 24,144 of 1906 (this J., 1907, 957), the vapours given off during the concentration and evaporation of the ammonium sulphate liquors are added to the air supply for the producer, or to a part of it, preferably at the outlet of the air saturating tower. The air supply to which the acid vapours have been added is passed through a washer containing heated alkaline liquor, and thence to the superheater. This alkaline liquor may be drawn from the mechanical gas-washer or from the ash-pit of the producer, and it is preferably kept at the desired temperature by circulating through a jacket around the gas main at the outlet of the superheater. The air leaves the alkaline washer saturated at 80° C., and less steam from auxiliary sources need be added than with the known types of plant. The economy thus effected is equivalent to 5 per cent. of the heat value of the coal gasified, and may amount to 10 per cent. with fuels such as peat which give large yields of ammonia.—A. T. L.

Gas-producer for the manufacture of gas free from tar. Soc. L. Bontillier et Cie. Fr. Pat. 399,160, April 11, 1908.

TWO producers are described, in each of which the gases formed from bituminous fuel in one producer chamber pass through a second producer chamber charged with fuel which has been coked in the first chamber. (1). The two chambers are superposed and the fuel column is continuous. Bituminous fuel is fed into the lower chamber at the bottom of the fuel column by means of a screw conveyor, and is evenly distributed by means of a rotating grate of inverted conical form. The producer is worked with an up-draught. The fuel is coked in the lower chamber and is forced up into the upper chamber as more fresh fuel is forced in. The tarry gas formed in the lower chamber passes through the coke in the upper

chamber and leaves the producer by an outlet above the fuel column. (2). The two chambers are arranged one above the other and each is provided with a grate and worked with an up-draught. Bituminous fuel is fed into the upper chamber from a hopper in the ordinary way, and the coked fuel is allowed to fall from time to time into the lower chamber through a valved pipe of large diameter which passes up centrally through the grate in the upper chamber. The tarry gas from the upper chamber is led by a down-pipe and delivered beneath the grate in the lower chamber. The gas, mixed with air, passes up through the coked fuel and leaves by an outlet in the upper part of the lower chamber.

—A. T. L.

Gas producers. W. B. Chapman. Fr. Pat. 399,203 Feb. 6, 1909.

THE cylindrical shell of the producer is formed of several independent rings or sections which are rotated at different speeds, one or more of these sections including the upper most remaining fixed. One of the rotating sections is provided with a water-cooled tube which passes across the interior of the producer and aids the rotary movement of the fuel. A charging hopper is mounted on the top plate near the walls of the producer, and a water-cooled depending bell is arranged beneath the hopper, and extends below the level of the gas outlet so as to form a coking-chamber. Gases from the upper part of this coking chamber are drawn by an injector through a down pipe and are delivered into the producer fire at or below the zone where the fuel is stirred and broken up by the water-cooled tube. The lowest section of the producer is rotated and carries an inverted conical shell extending downwards into the ash-pit. The inlet for air and steam is formed by a hollow pyramid arranged centrally in the ash-pit; and this pyramid in conjunction with the rotating conical shell serves to break up the cinders and aid their passage to the ash-pit. A conical cap, protecting the open top of the hollow pyramid, is provided with four arms or blades extending horizontally towards the walls of the producer but inclined similarly to propeller-blades so as to stir the rotating fuel column. Alternatively these arms or blades may be fixed to the lowest section of the rotating shell. The various improvements are described in connection with two producers, one of which is of the suction-type and suitable for use on ships.

—A. T. L.

Gas-producer plant yielding purified gas. Soc. Métallurgique de la Madeleine-lez-Lille. Fr. Pat. 399,295 Feb. 10, 1909.

THE producer, which is of the suction type but may be worked by means of a blower if desired, is provided with a removable producer chamber comprising a cylindrical iron casing lined internally with alternate rings of refractory material and of asbestos. This lining is sufficiently yielding to withstand shock and vibration, and renders the producer suitable for use on vehicles and boats. The gas is purified by passing it through a series of tubes provided with external cooling ribs, and fitted internally with removable spiral-shaped metal brushes. These tubes may be arranged horizontally beneath the floor of a vehicle, or they may be vertical.

—A. T. L.

Gas producer with central rotating grate. H. Küpper. Fr. Pat. 399,562, Feb. 16, 1909.

THE body portion of the producer and a central conical grate, which are rotated in opposite directions, are provided with sharp wedge-shaped projections to break up the clinker and facilitate its passage to the ash-pit. The rotating portion of the shell of the producer is sealed in water both at the lower and at the upper end. The lower part of this rotating shell is formed with an outer casing through which water is circulated for cooling the shell and the projections. The conical grate is formed of three superposed ring-shaped castings having sharp projections as described, the uppermost and smallest ring being surmounted by an oblique conical casting which is kept cool by admitting steam within it. The

gs are spaced apart sufficiently to allow the air and am which are delivered within the grate to pass between m into the producer.—A. T. L.

s-testing burner for producer gas plants. E. G. Hiller, and The National Boiler and General Insurance Co., Manchester. Eng. Pat. 16,157, July 30, 1908.

E burner comprises a cylindrical cleansing chamber h a gauze cap or hood forming the burner orifice. A bin, having flanges of cruciform shape, and wound with led wire, is placed vertically within the cleansing mber, the upper flange resting on the walls of this mber, so as to suspend the bobbin within it. The mber is enlarged at the lower end so that the gas has access to the coils of wire, which intercept tar, etc. en used with suction gas producers, the gauze of the ner prevents the passage of flame inwards should a it be applied while the engine is at work.—A. T. L.

cleaners [for blast-furnace gas]. J. Ruddiman, Yonkers, Vestchester, U.S.A. Eng. Pat. 5572, March 8, 1909.

apparatus comprises an inner dry dust-collecting ber, 7, arranged beneath the gas inlet pipe, 4, and annular chambers, 11, 12, in which the gas is further ed by impinging on the surface of the water in the part of the cleaner. The gas passes from the ber, 11, to the chamber, 12, through a number of tubes, 14, reaching nearly to the surface of the water. Inner chamber, 7, is kept cool by the water which unds the lower part of it. The scum on the surface e water is carried away through outlets, 17, into an ar chamber, 18, provided with a drain-pipe, 20. water inlet nozzles, 22, are arranged so as to direct ow of scum towards the outlets.—A. T. L.

ndescent gas mantles. J. W. Layton-Fisk, Cardiff. Eng. Pat. 4860, Feb. 27, 1909.

inforce and strengthen ordinary mantles, these are d in a solution obtained "by melting silica with its weight of potassium or sodium silicate in solution, diluting the mixture with distilled water." The mantle n dried and placed over a Bunsen flame, and whilst arm, is sprayed with a dry finely-powdered mixture ee parts of talc and 1 part of "muschelkalk alk one."—A. T. L.

Incandescent gas mantles. J. Fellner, London. From Oherfelt und Co., Berlin. Eng. Pat. 5260, March 4, 1909.

AFTER the fabric of the mantle has been impregnated, reinforcing threads which have been previously inapreg-nated and hardened are threaded through it and secured with the mantle to the carrier ring. The hardening of the reinforcing threads may be effected by adding didymium and beryllium nitrates to the solution with which the threads are impregnated.—A. T. L.

Metallic filaments for electric incandescent lamps, and manufacture of same. H. Kuzel. Fr. Pat. 399,007, Jan. 20, 1909. Under Int. Conv., Feb. 22, 1908.

FILAMENTS bent to a horse-shoe or U-shape are manu-factured by suitably loading the filament with weights or springs. The weights or springs are attached to the filament by hooks or clips formed of insulating material, or by hangers which bear upon a length of the filament so as to give it the desired curvature. The bend of the U-shaped filament may thus be curved in any desired manner, or it may be made right-angled or polygonal. The shaping of the filament may be effected during its manufacture or after it is finished.—A. T. L.

Peat and like vegetable fibrous materials; Method of depriving — of superfluous moisture. M. Ziegler, München, and Oberbayerische Kokswerke und Fabr. Chem. Produkte, Beuerburg, Germany. Eng. Pat. 16,792, Aug. 10, 1908.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Naphthalene. Sulphonation of —; Quantitative examina-tion. P. C. J. Euwes. Rec. Trav. Chim. Pays-Bas, 1909, 28, 298-338.

THE author finds that when 1 mol. of naphthalene is heated, at 50° C., with 1 mol. of sulphuric acid, the α -sulphonic acid is formed in an almost pure state; as the temperature is raised to 150°–160° C., the amount of β -acid increases to a maximum. On heating to a still higher temperature, disulphonic acids and sulphonates are formed in increasing quantities and the amount of unattacked naphthalene decreases. The duration of the heating has much influence on the product; the primary product is the α -acid which is transformed into the β -acid. Nevertheless at the temperatures 143° C. and 158° C. an equilibrium between the two acids is attained. This equilibrium is probably due to hydrolysis of the two acids, with formation of naphthalene and sulphuric acid.

At 129° C. the process is more complicated as an intramolec-ular change of α -acid into β -acid probably takes place at the same time. The presence of water accelerates the attainment of equilibrium very greatly; after addition of 4 per cent. of water, equilibrium was attained after heating for two hours, whereas in absence of water six hours

heating was required. The quantity of unattacked naphthalene was greater in the presence of water. In presence of sulphur trioxide, disulphonic acid was obtained, whilst addition of phosphorus pentoxide caused the formation of sulphones. The sulphates of mercury and lead did not influence the rapidity with which equilibrium was attained. —E. F.

Baku petroleum: Filtration of — through fullers' earth. V. F. Herr. *Petroleum*, 1909, 4, 1284-1287.

A FILTERING layer of sufficient thickness separates from the crude oil all the unsaturated, high-molecular, aromatic and similar bodies that give the Nastjukoff "formolite" reaction (this J., 1904, 1082). On the other hand, the naphthenes, dinaphthenes, paraffins, and in fact all the bodies that do not give the above reaction (small quantities of benzene homologues being left out of consideration) pass through the filtering medium. —C. S.

Petroleum industry of Galicia. Board of Trade J., Aug. 26, 1909. [T.R.]

THE year 1908 was marked by greatly increased production and such unprecedentedly low prices that many of the oil producers were threatened with ruin. By the end of 1907 the price of crude oil had fallen to 1s. 3d. per 100 kilos. During the first three months of 1908 there was a slight rise in prices, but in April and May a number of new wells were struck, and the enormous over-production which followed caused the greatest embarrassment to the industry, while the existing storage and railway transport arrangements proved totally inadequate.

In view of the critical condition of the industry, the Austrian Railway Minister promised to introduce the use of oil instead of coal on the State railways in Galicia; he also arranged for improved transport facilities. A provincial association of oil producers, representing 80 per cent. of the total production, was formed, and this body made a contract with the State railways for the delivery of 220,000 metric tons of oil per annum. The railway authorities, however, found that it was not safe to use the oil in its crude state in railway locomotives, but that the benzene would have to be extracted first. The Producers' Association had not the capital to build the necessary works for this process, or the new reservoirs required; accordingly, the Government undertook to build a factory for extracting the benzene at Drohobycz, and to lease it to a cartel of the Austrian refineries which is being formed, and which will undertake to purify the oil for the use of the State railways. The State will pay the Producers' Association direct for the crude oil required at a price considerably higher than the present market price, and which has been fixed with reference to the cost of the coal that would have been required for the locomotives. The State will further build the reservoirs and lease them to the oil miners at a rate just sufficient to cover the interest and amortisation of the capital. The Government has introduced a Bill in the Reichsrath by which a concession will in future be necessary for carrying on the business of storing, handling, and refining crude oil in Austria, and the provincial authorities will be empowered to refuse this concession at their discretion.

In 1908 the amount of crude oil produced in Galicia was 1,734,235 metric tons, as compared with 1,175,974 tons in 1907 and 760,443 tons in 1906; 15,906 metric tons of mineral oils were imported into Austria-Hungary in 1908, as compared with 18,816 tons in 1907 and 27,339 tons in 1906; and 370,600 tons were exported in 1908, as compared with 217,258 and 195,885 tons respectively in 1907 and 1906. The export of mineral oils from the Monarchy, chiefly in the shape of refined petroleum or benzene, has risen enormously during the last few years, having increased proportionately more rapidly than the total production, of which it now forms about the fifth part. Nearly two-thirds of the export are sent to Germany; then follow France, Switzerland, Turkey, Italy, and the United Kingdom, the last-named country only taking 4500 tons. In 1906, 12,521 tons of paraffin wax were produced in Austria, of which 11,371 tons were exported; in 1907, 15,937 tons were produced, the export being 14,737 tons, and in 1908, 28,520 tons were produced and 27,220 tons exported, of which 1,660 tons went to the United Kingdom. The

total production of ozokerite in Boryslaw during 1908 was 2,050 tons; of this 675 tons were shipped from Hamburg and Stettin to America and the United Kingdom, and 1,222 tons were consumed on the Continent.

PATENTS.

Agglomeration of charcoal obtained by the distillation of olive kernels in closed vessels. Las Industrias del Olivo. Fr. Pat. 399,341, Dec. 18, 1908.

THE carbonaceous residue left in the retort after distilling olive kernels is roughly powdered and agglomerated with starch paste. A small proportion of sodium potassium nitrate or other oxidiser is added to facilitate the combustion of the product. After mixing, agglomerating and forming into balls, the latter are dried either in the air or in stoves. —W. H. C.

Woody residues [olive kernels]: Process for the continuous distillation of —. Las Industrias del Olivo. Fr. Pat. 399,342, Dec. 18, 1908.

THE materials to be distilled are fed through a charging hopper into the upper end of a vertical cylindrical retort set in a furnace. A number of metal frustums of cones are superposed within the retort which is provided with a hopper at its lower end for the discharge of the solid residue and is also connected both at the top and at the bottom to a condenser. —W. H. C.

Coal-tar: Process for obtaining mineral grease and agglomerated coke by distillation of —. S. J. Sauvage. Fr. Pat. 399,359, Jan. 20, 1909.

A MIXTURE of 100 parts of coke dust, 50 parts of coal-tar, 5 parts of lime and 15 parts of water is heated and distilled for four hours at a temperature of from 800° to 1000°. Mineral grease and an inflammable gas distil over at agglomerated coke is left behind in the retort. —W. H. C.

Tar, tar-oils, resin oils and other similar distillate products: Process for the purification of —. Sprenger. Fr. Pat. 399,760, Feb. 8, 1909. Und. Int. Conv., Jan. 5, 1909.

THE oils, after being washed with caustic alkali solution in the ordinary manner to remove phenols, etc., are heated either with or without pressure with another portion of caustic alkali solution and a metal in a fine divided condition. This treatment renders the resin and other similar impurities soluble in water. The oil is separated, washed once or twice with hot water and then redistilled. It is stated that oils treated in this manner undergo oxidation in addition and that after redistillation they are not liable to darken in colour on standing. —W. H. C.

Lead bath dissociator for hydrocarbons and all industrial residues. E. A. Barbet. Fr. Pat. 399,722, April 2, 1908.

THE hydrocarbons to be treated are introduced in a continuous stream below the surface of molten lead contained in a closed vessel set in a furnace and provided with a pipe leading to a condenser. The hydrocarbons are vaporised by the heat and the bubbles of vapor rise up through the lead and impinge upon the under surface of a flat hood, which is suspended just below the surface of the molten metal. The flat top of the hood is corrugated, and it is suspended by rods which pass through the cover of the vessel and are attached to external screws so that the inclination of the flat hood and the depth to which it is immersed can be varied without opening the vessel. By this means the time of contact between the vaporised hydrocarbon and the molten lead can be varied in order to obtain at will either liquid gaseous products. —W. H. C.

Oxidising agent: New —, and method of manufacture. Soc. Electrolytique des Acétates Français. Fr. Pat. 399,937, May 8, 1908.

WOOD charcoal is boiled with dilute hydrochloric acid, washed and then boiled with distilled water, dried, and calcined in a closed vessel. When cool the product

exposed to oxygen under pressure. The oxygen is condensed within the pores of the charcoal which, it is said, then forms an energetic oxidising agent. The charcoal thus treated is used to convert alcohol into dehyde and acetic acid.—W. H. C.

IV.—COLOURING MATTERS AND DYE STUFFS.

Dye stuff industry of Germany and the new American Customs tariff. Chem. Zeit., 1909, 33, 875. [T.R.]

THE German dyestuff industry is seriously affected by a new American tariff. Although the tax (30 per cent. of the value) on dyestuffs remains the same, the following materials are now admitted free:—Naphthylamine- and naphthol-sulphonic acids and their sodium and potassium salts, aminonaphtholsulphonic acids, aminosalicic acid, nitrochlorobenzene, diaminostilbenedisulphonic acid, etanilic acid, *p*-nitraniline and dimethylaniline. The American manufacturers can thus produce many important dyestuffs from duty-free materials, and so compete with the imported German goods. As a consequence of this competition it will be necessary for German firms to erect branch works in the United States.—J. C. C.

PATENTS.

Aminobenzonitrile and its substitution products; Process for preparing —. Kalle und Co., A.-G. Ger. Pat. 212,207, Dec. 6, 1907.

Good yields of *o*-aminobenzonitrile, and its derivatives are obtained from *o*-nitrobenzonitrile or its derivatives by reduction with iron and acetic or hydrochloric acid at temperatures not exceeding 70° C.—T. F. B.

Aminoanthraquinones; Process for preparing —. Badische Anilin und Soda Fabrik. Ger. Pat. 211,958, July 16, 1908.

TO OBTAIN aminoanthraquinone derivatives, *e.g.*, the halogen derivatives, are only partially acetylated by acetic hydride in presence of sodium acetate. If, however, the acetylation is carried out by acetic acid or anhydride in presence of fuming or concentrated sulphuric acid, the reaction is complete and rapid. The process is applicable to all primary and secondary aminoanthraquinones and their derivatives.—T. F. B.

Aromatic carboxylic acids from the corresponding aldehydes; Process for preparing negatively substituted —. Badische Anilin und Soda Fabrik. Ger. Pat. 211,959, Aug. 2, 1908.

NEGATIVELY substituted aromatic aldehydes are easily converted to the corresponding carboxylic acids, without formation of chlorine substitution products, by treatment with hypochlorite solutions in presence of alkali. The process is suitable for the oxidation of nitrobenzaldehydes, benzaldehyde sulphonic and carboxylic acids, etc. —T. F. B.

Colouring matters of the anthracene series; Manufacture of —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 12,167, June 4, 1908.

SEE Fr. Pat. 390,677 of 1908; this J., 1908, 1107.—T. F. B.

Uses of leuco compounds of indigo colouring matters; Manufacture and use of —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 24,605, Nov. 16, 1908.

V.—PREPARING, BLEACHING, DYEING, PRINTING AND FINISHING TEXTILES, YARNS, AND FIBRES.

Textile materials; Electrical charge of — when immersed in water or solutions of electrolytes. J. L. des Bancelles. Comptes rend., 1909, 149, 316–319.

IN connection with the theory of dyeing, the author has studied the electrical charge assumed by textile materials when immersed in various liquids. In order to determine this charge, the author used Perrin's apparatus, consisting of a U-tube containing the liquid and a porous plug of

the substance to be investigated in one of the branches of the U. When this tube is placed in an electric field, some of the liquid passes through the diaphragm, and this migration indicates the sign and the magnitude of the electric charge assumed by the substance in presence of the particular liquid. The electric field employed measured about 12 volts per centimetre. In presence of distilled water the common textile materials assume a negative charge; wool takes a higher charge than cotton and unboiled silk. In presence of an alkaline solution the charge increases without changing its sign. In acid liquids it decreases and may even change its sign; this has so far only been observed in the case of silk, because the concentration of acid is limited to below $N/500$ owing to the evolution of gas. The presence of polyvalent ions modifies the electrical charge of the textiles. When these are immersed in alkaline liquids or water, the negative charge decreases under the action of positive ions (barium, calcium, zinc) and increases under that of negative ions (sulphate, ferrocyanide). The textile materials obey in general the laws established by Perrin in his researches on electrification by contact. Mordanting appears to effect no appreciable modification of the charge assumed by textiles in water. On the other hand, dyed textiles show different charges from undyed; dyeing with Methylene Blue considerably lowers the charge taken by wool; this is possibly due to the presence of free ions of Methylene Blue.—J. F. B.

Dyeing air and fur. F. J.—G. Beltzer. Rev. Gen. Mat. Col., 1909, 13, 187, 224.

AN account is given of the Green process for dyeing Aniline Blacks on hair and fur. This process is based upon a catalytic action produced by a small quantity of a para-diamine or a paraminophenol in the dye liquor. The catalyst serves to convey atmospheric oxygen to an aniline salt in its oxidation to Aniline Black. The great advantage of the method is that the aniline salts of organic acids may be employed. Paraphenylenediamine, diparaminodiphenylamine, diparaminoditolylamine, benzidine, tolidine, diamidine, diparaminophenylmethane, and their analogues, homologues, and derivatives (sulphonic, carboxylic, etc.) can be employed as the catalyst. Substances which yield a *p*-diamine can also be used, such as quinone-imines, *p*-nitrosophenol, *p*-nitrodimethylaniline, *p*-aminophenyl-quinone-monoxide, and their analogues, homologues and derivatives. Formule are given for utilising the process to give "raven blacks," "brown blacks," "red blacks," etc., using either methods of brush dyeing, or immersion methods.—H. G. B.

Dyeing: The intervention of osmotic pressure in —. Rosenstiehl. Comptes rend., 1909, 149, 396–399.

THE author points out that, under the influence of pressure, solid substances can be made to adhere rigidly to one another and regards the process of dyeing as a similar phenomenon. The necessary pressure in the dye-bath is provided by the osmotic pressure which is increased when salts (or, in the case of wool and silk, sulphuric acid) are added to the bath.—J. C. C.

PATENTS.

Ammoniacal copper oxide [Cuprammonium] solutions for spinning artificial threads and the like; Process of producing —. P. Friedrich, Berlin. Eng. Pat. 4104, Feb. 19, 1909. Under Int. Conv., Feb. 19, 1908.

"AMMONIACAL copper oxide cellulose solutions," which can only be produced and preserved at low temperatures, acquire a high degree of permanence when "carbohydrates" are incorporated in them, and the products obtained from these solutions are exceedingly waterproof and elastic. If the ammonia be caused to evaporate, such a stable solution behaves quite differently from a pure ammoniacal copper oxide cellulose solution, which, as soon as its percentage of ammonia falls below 70 grms. per litre, is no longer able to keep in solution the entire quantity of cellulose, becoming gradually converted into a rigid, brittle, non-transparent blue mass. Under like conditions, solid precipitates are not thrown down from the new

solutions; on the contrary they remain quite homogeneous, but increase in toughness as the ammonia escapes from them. When the ammonia has entirely evaporated caoutchouc-like, but perfectly transparent product remain behind which, when dried finally, harden, but keep their transparency. The new solutions may also be coagulated by the ordinary precipitation methods. Example:—An ammoniacal copper oxide cellulose solution containing 7 per cent. of cellulose is prepared in a kneading machine in one of the known ways, a small quantity of glycerin being mixed with the ammonia. No more ammonia is used than is equivalent to the weight of cellulose. About 35 per cent. of "potato syrup (glucose)," reckoned on the weight of cellulose (the syrup containing about 30 per cent. of solid matter in solution), is added gradually to the solution, and the whole mass is kneaded for some time.—P. F. C.

Carbonising rays and other materials; Machine for —. J. Fitton, Ossett, Yorkshire. Eng. Pat. 16,692, Aug. 8, 1908.

A CYLINDER, *a*, is provided with hollow trunnions, *l*, for the admission of the gases by which the carbonisation of the material is effected. One section of the circumference of the cylinder is left open, and on the lower portions of the side plates are attached brackets, *c*, which carry rails, *d*, projecting at each end a little beyond the side plates. In alignment with the rails, *d*, are rails, *c*, leading from the machine to the drying room. Adapted to fit into and close up the open section of the cylinder, is a wagon, *f*, sufficiently large to hold enough material for one carbonisation and provided with wheel *h*, which will run on the rails, *d*, and abut against a stop plate, *g*. The wagon is held in this position by sliding bars, *h*, supported by the front of the wagon and adapted to fit into holes or recesses in the end plates. At the upper portion of the entrance opening to the cylinder is a stay, *g*¹, which in conjunction with a lip, *f*², on the front end of the wagon at its upper side forms a device for preventing undue escape of gases from the cylinder. The wagon revolves bodily with the cylinder, the material therein being distributed by means of forks, *l*. The apparatus rotates during the carbonising process in the direction of the arrow, *B*. When the process is completed the cylinder is partially rotated in the opposite direction to permit the material to fall into the wagon which is then withdrawn along the rails, *d* and *c*. The apparatus may be provided with a balance plate, *m*. —P. F. C.

Wool scouring by electricity. B. Lagye and R. Vandatto. Fr. Pat. 399,875, Feb. 24, 1909.

AN ordinary wool-scouring machine is employed, and current of electricity is made to pass between the prongs of the rakes which are used to draw the wool through the machine. As the wool passes between these prongs the action of the current assists in removing the foreign

natter clinging to the fibre. This scouring action is uniform, and is not attended by any shrinking of the fibre.—S. H. H.

Bleaching of textile fibres. J. Vernier. Fr. Pat. 398,985, Apr. 7, 1908.

THE process is designed for the bleaching of textile fibre, specially silk, in a cold bath and with only one treatment. The bath contains hydrogen peroxide, ammonia, and water. For example, 1 kilo. of silk is immersed in a bath containing 500 grms. of hydrogen peroxide, 20 grms. of ammonia, and 3 litres of water for 10 hours; the silk is then rinsed in water.—S. H. H.

Mercerising cloth; Process and apparatus for —. Heberlein et Cie. Fr. Pat. 399,904, Feb. 25, 1909.

THIS machine differs from other mercerising machines in that the rinsing with water takes place directly the cloth leaves the impregnating mangle and not after the full width has been attained by stretching. In this way the stretching force is applied gradually and is capable of regulation to enable the machine to be used on all classes of fabrics. The extension is caused by a series of curved bar expanders. The cloth passes through the caustic soda lye, is squeezed, again impregnated, and again squeezed before passing out of the mangle on to the expanders. Two of these expanders are placed above the wash water and six others below. After travelling over these, the cloth is again squeezed before passing into a second wash-box also containing expanders. A third wash-box contains more expanders; a fourth simply gives a final rinse. The recovery of the caustic soda by this counter-current system is said to be very efficient.—S. H. H.

Dyeing, bleaching and washing machine. N. Labonty, Woonsocket, R.I. U.S. Pat. 929,314, July 27, 1909.

THE material to be treated is arranged inside a cage, which is mounted so that it can slide piston-wise inside a closed operating tank, which is connected by supply pipes with a storage tank containing the liquid necessary for the treatment. The cage is drawn backwards and forwards by a piston rod, and means are provided for forcing liquid into the operating tank at opposite ends alternately.—P. F. C.

Dyeing machine. D. Gillies, Kidderminster. Eng. Pat. 15,997, July 28, 1908.

HORIZONTAL beam, *a*, of channel section, is arranged so as to extend across a rectangular dye-vat, *b*. This beam, secured at one end to a vertical standard, *c*, carries reciprocating carriage, *e*, which is provided with hank-

supporting poles, *d*. The carriage can be raised or lowered by ropes, *f*, which are connected to the carriage at one end by hooks, *g*, and can be wound at the other end around a drum, *h*. The poles, *d*, extend on each side of the beam, *a*, and are rotatably mounted on the carriage. Upon the axis of each pair of poles, a ratchet wheel, *m*, is eccentrically mounted, and each ratchet is provided with a pair of pawls. The first, *n*, secured to the beam below the ratchet, produces the rotation of the poles; the second, *o*, mounted on the carriage above the ratchet, prevents a return motion produced by the weight of the hanks. Reciprocation of the carriage on the beam is effected by a crank disc, *p*, a connecting rod, *q*, and worm gearing, *r*. The poles are loaded with hanks with the carriage in an elevated position. The carriage is then lowered to convey the hanks into the vat, and the reciprocating mechanism is set in motion. The hanks have then a triple motion. They are swayed to and fro by the reciprocating movement of the carriage, they are rotated by the action of the stationary pawls on the ratchets, and lastly, owing to the eccentricity of the poles they are moved upwards and downwards.—P. F. C.

Dyeing yarns, fabrics, and the like; Apparatus for —. C. Corron, St. Chamond, France. U.S. Pat. 929,562, July 27, 1909.

THE material to be dyed is hung over a number of eccentric rotatable reels which are arranged above the dye-vat, alternate reels being rotated in opposite directions. The driving gear can be reversed in direction and varied in speed. Means are provided for raising or lowering the framework which carries the reels.—P. F. C.

Dyeing cotton and analogous fibres with sulphide dyestuffs. F. H. E. Dupetit. Fr. Pat. 399,124, Apr. 9, 1908.

THE cotton is dyed in a bath containing the sulphide dyestuff, sodium sulphide, and sodium carbonate, and is then passed into dilute acetic acid. In this way carbon dioxide is liberated from the carbonate and sulphuretted hydrogen from the sulphide; the carbon dioxide gas prevents the reduced dyestuff from becoming oxidised on the fibre, and the sulphuretted hydrogen reduces any particles of dyestuff on the fibre which have already become oxidised. The oxidation takes place on washing with water and may be completed by a weak oxidising bath.—S. H. H.

Resist effects and resist pastes for vat dyeing; Production of —. J. Y. Johnson, London. From The Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 25,312, Nov. 24, 1908.

THE process is carried out by printing on the material a resist paste containing a soluble manganese salt and an oxidising agent, and then dyeing the material with the vat dyestuff according to the usual methods. Among the vat dyestuffs which can be resisted in this manner are indigo, thioindigo, the indanthrene dyestuffs, and the sulphur dyestuffs. Coloured resists can be obtained by using material which has been prepared with sodium β -naphtholate and subsequently applying a diazo-compound, either mixed with the reserve paste or otherwise. *Example* :— Resist for white: Dissolve 500 grms. of manganous chloride in 350 grms. of a 50 per cent. gum thickening and then add 75 grms. of china clay, 25 grms. of sodium bichromate, and 50 grms. of water, and stir well.—P. F. C.

Indanthrene dyestuffs; Process for reserving —. Kalle and Co. Ger. Pat. 211,526, June 15, 1906. Addition to Ger. Pat. 210,682, May 23, 1906 (see this J., 1909, 833).

THE process described in the principal patent for pro-

ducing white and coloured reserves under indigo, thio-indigo, and sulphide dyestuffs, may also be applied to indanthrene dyestuffs. —T. F. B.

Multicolour effects on fabrics of vegetable fibres and artificial silk: Process for producing —. E. Dierichs. Ger. Pat. 211,956, Nov. 14, 1907.

DYED cotton fibres are woven with undyed artificial silk, and the fabric thus obtained is treated with an alkaline solution, whereby the colour is partially discharged from the cotton and is taken up by the artificial silk. An example is given in which two lots of cotton are mordanted with tannin and dyed with Methylene Blue and Brilliant Rhoduline Red; the fabric made from these and the artificial silk is treated for half to three-quarters of an hour, at 40–50° C., with a 1 per cent. solution of sodium sulphide. —T. F. B.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Boric acid: Volatilisation of —, by ignition in a stream of carbon tetrachloride and methyl alcohol vapours. P. Jannasch and H. F. Harwood. J. pr. Chem., 1909, 80, 131.

CARBOXY tetrachloride vapour alone does not decompose boric acid, but when boric acid is heated to dull redness in a stream of the mixed vapours of carbon tetrachloride and methyl alcohol it is readily and completely volatilised. Probably a mixture of these two vapours with hydrochloric acid gas would volatilise the boric acid from borates. —J. T. D.

Ammonia: The solid hydrates of —. F. F. Rupert. J. Amer. Chem. Soc., 1909, 31, 866–868.

WITH aqueous solutions of ammonia, maximum freezing-points, each –79° C., were obtained when the quantities of ammonia present were 49 per cent. and 65 per cent. These proportions correspond respectively to the hydrates $\text{NH}_3 \cdot \text{H}_2\text{O}$ (monohydrate) and $2\text{NH}_3 \cdot \text{H}_2\text{O}$ (semihydrate), the theoretical percentages of ammonia being 48.59 in the former and 65.40 in the latter. The monohydrate was

obtained in very small colourless crystals, suggestive in appearance of sodium and potassium hydroxides, the crystals of the semihydrate being much larger, transparent, and needle-shaped. Solutions containing from about 25 to 60 per cent. of ammonia are very viscous at temperatures below about –60° C. At –100° C. the 33 per cent. solution can hardly be stirred. —W. E. F. P.

Chlorine: Manufacture of anhydrous — from moist dilute gases, and its industrial application in chlorine detinning. E. A. Sperry. J. Ind. and Eng. Chem., 1909, 1, 511–518.

THE chlorine produced in electrolytic processes is generally diluted with other gases and saturated or supersaturated with moisture. By subjecting such gases to the action of a spray of diluted brine, practically the whole of the chlorine separates in the form of solid chlorine hydrate which can be separated from the brine. The hydrate is subsequently decomposed by using it to chill the supplies of brine and of crude gas, and by utilising the heat developed in compressing the anhydrous chlorine gas preparatory to liquefaction, in the final stage of the process. The chlorine gas liberated from the hydrate is again refrigerated in order to completely free it from moisture and is then compressed and liquefied. It is stated that in the near future liquefied chlorine will be as easily obtainable on the American market as it has been for some years in Germany. The most important application of the liquefied chlorine is the detinning of tin-plate scrap. It is important that the scrap be perfectly dry, since as little as 1 per cent. of moisture is sufficient to convert practically all of the stannic chloride produced into solid hydrated chloride, which cannot readily be distilled or purified, and which adheres tenaciously to the iron scrap. The crude scrap is compressed into billets, cleaned, heated to considerably above 100° C., and treated with the anhydrous chlorine in a suitable reaction vessel, being subjected to a comparatively small centrifugal action during the reaction, in order to facilitate the penetration of the chlorine and expose fresh surfaces of the scrap. It is stated that several tons of scrap may be thoroughly detinned in 60–90 mins. with a relatively small apparatus. The resulting "black scrap" is freed from stannic chloride by steam, and then from any ferric chloride produced, and is afterwards made the cathode in an electrolyte consisting of a hot, weak alkaline lye. If a current of about 300 amperes per ton of scrap be passed for about 30 mins., it is stated the treated scrap can subsequently be exposed to ordinary weather conditions for upwards of a year without serious depreciation. (See also this J., 1907, 1279; 1908, 26, 128, 160, 287, 343, 404, 451, 628, 749, 985). —A. S.

Phosphoric acid: Quantitative volatilisation of —, and separation from the metals of the ammonium sulphide group. Jannasch and Jilks. See XXIII., Inorg. Quantit.

Vanadic acid: Quantitative volatilisation of —, from its compounds by ignition in a stream of carbon tetrachloride vapour. Jannasch and Harwood. See XXIII., Inorg. Quantit.

Nitrates from air: Manufacture of — in Germany. Board of Trade J., Aug. 19, 1909. [T.R.]

IS full working order the principal German works at present engaged in the manufacture of calcium nitrate can produce about 21,500 tons per annum, a quantity which will be increased to about 41,500 tons when the plant now in course of construction is completed and in operation. Projects for a number of other works are under consideration, the most important of which is that of a company which is contemplating the erection of large nitrate works in Bavaria. A factory has also been built in the Tyrol by a Westphalian company, and is capable of producing about 3600 tons of nitric acid. It is estimated that 1300 tons of nitrate of lime were sold in Germany in January and February last.

Barium compounds; Production of — in the United States. U.S. Geol. Survey, 1909. [T.R.]

THE following table shows the production of crude barytes in the United States since 1900:—

	Tons.		Tons.
1901.....	49,070	1905.....	48,235
1902.....	61,668	1906.....	50,231
1903.....	50,397	1907.....	89,621
1904.....	65,727	1908.....	34,615

After the panic in the latter part of 1907 the trade in barytes products came practically to a standstill, and mills that operated at all during 1908 had nearly sufficient material on hand to last throughout that year, consequently the production of the mines was greatly curtailed.

The average price of crude barytes per short ton (\$3.20) in 1908 was only 6 cents less than in 1907, and it was higher than in any year except 1907. Prices per short ton quoted by dealers toward the close of 1908 were as follows:—"American ground," \$14 to \$17.50, and "floated," \$18 to \$21; in May, 1909, these prices were respectively, \$12 to \$17, and \$17 to \$20.

The total quantity of barytes reported as refined by mills in Kentucky, Missouri, North Carolina, Tennessee and Virginia was 28,415 short tons, valued at \$318,096, an average price per ton at the mills of \$11.19, a decrease of 23.3 per cent. as compared with \$14.59 per ton in 1907.

At the close of 1908 there were 16,471 short tons of crude barytes unsold, according to the reports from all the producing districts. Most of this stock was produced in 1907.

The imports of barytes for consumption during the last five years and the imports of barium compounds during the last three years have been as follows:—

Barytes.

Sicilian sulphur industry; Bill for regulating the —. Board of Trade J., Aug. 19, 1909. [T.R.]

A BILL for the regulation of the sulphur industry has been presented to the Italian Parliament by the Minister of Agriculture, Industry, and Commerce. It modifies and is intended to take the place of the Laws of 15th July, 1906, 6th June, 1907, and 5th July, 1908, relative to the institution of the obligatory "Consortio" or Association of sulphur mine owners. The object of the principal modifications is: (1) To simplify administration and reduce the number of Directors; (2) to authorise the "Consortio" to cede to one party or company the sale of its total production for the whole term of the former's existence (12 years from 1st August, 1906); and (3) to restrict the output as far as possible to the consumption.

PATENTS.

Nitric oxide; Concentration of — [arising out of the electrical oxidation of atmospheric nitrogen]. Allgem. Elektrizitäts-Ges.m.b.H., Berlin. Eng. Pat. 8426, Apr. 15, 1908. Under Int. Conv., Apr. 19, 1907.

THE oxides of nitrogen are first absorbed in a suitable apparatus by a weak basic oxide, such as oxide of zinc, copper, or lead, and the mixture of nitrate and nitrite so obtained, is subsequently decomposed at a higher temperature, under reduced pressure it desired, with evolution of pure nitrogen peroxide.—O. R.

Nitric acid; Manufacture of —. F. L. Schmidt, Charlottenburg, Germany. U.S. Pat. 928,545, July 20, 1909.

CALCIUM nitrate is decomposed with the equivalent quantity of sulphuric acid, and the calcium sulphate, which is deposited, is filtered and washed with dilute nitric acid and water.—O. R.

Sulphuric acid; Concentration of — in Kessler's apparatus. J. Teisset and L. Prat. Fr. Pat. 398,212, Dec. 31, 1908.

IN the ordinary Kessler apparatus, the parallel channels, in which concentration takes place, are replaced by transverse baffles of refractory material. An external fan aspirates the gases through the apparatus, with consequent increased yield of sulphuric acid, and a regenerative system of heating causes much more rapid concentration in the saturating tower.—O. R.

Pyrites; Mechanical furnace for roasting —, with distributor and dust chambers. F. L. Coureau. Fr. Pat. 399,479, Feb. 15, 1909.

THE furnace consists of a number of superposed hearths, over which rakes and other tools for turning over and carrying forward the pyrites or other material are made to travel, by means of parallel endless chains on either side of the furnace. After passing backwards and forwards alternately over the hearths from the top to the bottom of the furnace, each rake passes out through a door opening automatically, and then travels upwards, becoming cooled in the process, and into the furnace again by another door at the top. The material is fed into the furnace by an automatic registering device, the rate of feed being regulated by that at which the material is being carried forward and discharged. In order to secure regular combustion and prevent leakage of air into the furnace, this and the mechanism is cased in sheet iron, the necessary doors being fitted with asbestos. The raking tools are very readily replaced, when occasion requires.—F. SOOX.

Alkali carbonates; Manufacture of —. L. Rivière. Second Addition, dated Jan. 30, 1909, to Fr. Pat. 396,448, Nov. 16, 1908. (See this J., 1909, 707.)

FOR the regeneration of hydrofluosilicic acid, silicon fluoride is made to react with hydrogen fluoride in the gaseous state, instead of in aqueous solution as in the principal patent, and the acid, thus produced, is collected in water or used directly for the production of alkali fluosilicates. By way of example, an apparatus is described for the simultaneous decomposition of the alkali fluosilicate, as in the First Addition (*loc. cit.*), and for the continuous production of hydrogen fluoride, as also for the interaction of the gases. In this apparatus, the reacting vessels and crucibles are grouped around a common chimney, and there is a device for turning the covers and stirring gear of the hydrogen fluoride generators through an angle, so that, while one set of vessels is in use, another set is being recharged. Hydrogen fluoride is produced at such a rate, that it combines with all the silicon fluoride coming from the crucibles, the two gases being discharged into an annular reaction box running round the central chimney.—F. SOOX.

Sodium sulphate; Manufacture of —. D. A. Peniakoff, Selzaete, Belgium. Eng. Pat. 3189, July 10, 1908. Under Int. Conv., Jan. 29, 1908.

A MIXTURE of sulphur dioxide, superheated steam, and air, passes slowly into slightly inclined, revolving, iron

tubes, down which sodium chloride, powdered or briquetted, slowly descends in the reverse direction to the gaseous mixture. Means are provided for constantly stirring and raising the sodium chloride, and for exposing it to sulphurous gases of increasing activity as it descends, until it finally emerges, entirely converted into sodium sulphate. By mixing the sodium chloride with ferruginous bauxite, or other aluminous material containing ferric oxide, and subjecting the mixture to the same treatment as above, a product is obtained, which may be directly used for the manufacture of sodium aluminate.

—O. R.

Ammonium sulpho-phosphate for the treatment of vintages and musts, and its process of manufacture. A. Hubert. Fr. Pat. 399,142, Feb. 5, 1909.

AMMONIUM sulpho-phosphate is prepared by allowing mono-, di-, or tri-ammonium phosphate to absorb sulphur dioxide, or by mixing ammonium bisulphite with phosphoric acid or ammonium phosphate. The products, which may be solids, or in solution, are used for the treatment of vintages or musts.—F. SODX.

Copper sulphate; Direct manufacture of — from metallic copper. A. P. C. Pautin and L. J. A. Couvert. Fr. Pat. 399,413, April 21, 1908.

COPPER sulphate is manufactured directly from metallic copper by treating this with dilute sulphuric acid, in the presence of hot compressed air or a mixture of air and sulphur dioxide. Contact with lead is found to hasten the solution of the copper, though the lead is not itself attacked. The copper is packed in a series of leaden towers, generally three in number, and the mother liquors from previous crystallisations, containing the necessary acid, are pumped to the top of the first tower, to be distributed intermittently; this liquid, descending over the copper, meets an ascending current of hot compressed air, which is injected below and escapes through holes in the side of the tower into pipes which are sealed hydraulically; the solution collecting at the bottom of the tower passes by an overflow into a tank, from which it is pumped to the second tower which is similar; from the third tower, the now concentrated solution is sent to the crystallisers.—F. SODX.

New salts derived from alkali, alkaline-earth, and earth peroxides; Manufacture of —. G. F. Jaubert. Fr. Pat. 399,720, April 29, 1908.

THE new products, derived from any peroxide which may be used for the preparation of hydrogen peroxide,

are obtained by acting on the peroxide in question with any acid, organic or inorganic, or with an ester, either directly or in the presence of a medium, in which hydrogen peroxide is insoluble or nearly insoluble. The salts, thus formed, are very stable when dry; they contain all the active oxygen of the peroxide and are immediately dissociated by solution in water, hydrogen peroxide being liberated. Four examples are given:—(1), *Sodium perchloride*, which is prepared by slowly passing dry hydrogen chloride, with vigorous agitation, into 8 kilos. of sodium peroxide suspended in 100 litres of carbon tetrachloride, until 7.5 kilos. have been absorbed; (2), *sodium performate*, obtained by adding 9.5 kilos. of formic acid, drop by drop, to a similar mixture of the peroxide; (3), a salt produced by slowly adding 12 litres of ethyl acetate to 8 kilos. of sodium peroxide, suspended in 80 litres of chloroform; (4), *sodium perbenzoate*, prepared by mixing 12.5 kilos. of benzoic acid with 100 litres of carbon tetrachloride, and then gradually adding 4 kilos. of sodium peroxide. In all cases the temperature is kept below 30° C. during the process; the salts separate in the solid state.—F. SODX.

Oxides [especially ferric oxide]; Manufacture of —. H. L. Doherty, New York. U.S. Pat. 927,644, July 13, 1909.

Moist, finely-divided metallic iron, is oxidised by a current of air until the temperature begins to rise; the current of normal air is then replaced by a current of air diluted with nitrogen, until the temperature begins to sink, when normal air is again used to finish the reaction.—O. R.

Ammoniacal copper oxide; Process of obtaining stable solutions of —. Chem. Fabr. Bettenhausen Marquart und Schnlz. Fr. Pat. 399,911, Feb. 25, 1909. Under Int. Conv., Mar. 25, 1908.

THE stability of solutions of ammoniacal copper oxide may be increased by the addition of 1–2 per cent. of such substances as the polyhydric alcohols, sugars, starches, or gums. Moreover, by the previous addition of one of these substances, the preparation of the solution is facilitated, and the copper concentration may be increased to 5 per cent. or more, without cooling.—F. SODX.

Carbon dioxide; Separation [by liquefaction] of — from gaseous mixtures. J. G. Behrens. Fr. Pat. 397,767, Dec. 22, 1908.

THE compressed gases are passed through (a), the innermost of the three concentric tubes, (a), (b), and (c)

Condensation of carbon dioxide takes place in a receiver (*d*), from which the compressed, unliquefied gases pass into a turbine (*e*), which is divided into eight compartments. From each of these compartments (I.), (II.), (III.), etc., in turn, the compressed gases pass into the next compartments (II.), (III.), (IV.), etc., by way of spiral condensers (1), (2), (3), etc., which are situated inside the outer tube (*c*). In each passage from one compartment of the turbine to the next, the gases are allowed to expand till their pressure is reduced by one-eighth, the consequent absorption of heat serving to cool the tube (*e*), which is filled with alcohol. The cold produced in the latter is communicated to the tube (*a*) by the agency of the tube (*b*), in which carbon dioxide circulates; this carbon dioxide enters (*b*) in the liquid form through the tap (*f*), evaporates inside (*b*), and returns, at the extremity opposite to (*f*), in the gaseous form to the compressor.

—O. R.

Ozone: Apparatus for manufacturing — Felten und Guillaume-Lahmeyerwerke Act.-Ges., Frankfurt-on-Maine, Germany. Eng. Pat. 6014, Mar. 12, 1909. Under Int. Conv., Sept. 9, 1908.

The claim is for a control mechanism in conjunction with an apparatus used for ozonising water. The flow of water through the apparatus operates a switch, which closes the electrical circuit, a non-return valve being connected to the ozone-pipe between the switch and the ozone apparatus, to prevent water from getting into the latter.—O. R.

Air: Apparatus for liquefying — J. F. Place, Glenridge, N.J., Assignor to American Air Liquefying Co., New York. U.S. Pat. 927,594, July 13, 1909.

The apparatus consists of one or more high-pressure pipes, enclosed in a low-pressure conduit provided with a liquid air evaporating container; compressed air is supplied to one end of the pipe, and a high-pressure liquefying condenser is situated at the other end, having a liquid air discharging valve, which connects the condenser with the container. The condenser is so arranged as to be submerged in the liquid air previously produced in the container. Between the condenser and the compressed air supply, is a pressure releasing air valve, which is connected with the high-pressure pipe, and is arranged to deliver air from the high-pressure pipe to the low-pressure conduit.—O. R.

Liquefaction, in large quantities, of gas or mixtures of gases having a low critical temperature: Process and apparatus for the — [Separation of air into oxygen and nitrogen.] United States Liquid Air and Oxygen Co. Fr. Pat. 399,416, Dec. 8, 1908.

In this process for the liquefaction of air, all impurities liable to clog the apparatus are eliminated before the gas is allowed to enter the liquefier; this is effected by a preliminary regenerative cooling, in which the lowering of temperature is brought about by the almost adiabatic expansion of the gas itself, no other refrigerating agent being employed. The air is first compressed in several stages, preferably four, after each stage passing through a cooling arrangement in which water circulates. On leaving the last compressing cylinder, the gas, possibly at a temperature of 100° C. or more, passes through a trap, in which some of the accompanying oil and moisture are deposited, and then travels, in a divided circuit, through a cooler, consisting of multiple pipes of small diameter, in which the gas is rapidly cooled to the ordinary temperature by the surrounding air. It then passes successively through three regenerative coolers, all of which are so arranged that oil and water, condensing from the gas, may drain into appropriate traps. After this, it is allowed to expand almost adiabatically, doing external work in some form of expansion engine, the gas being more effectively cooled in this way than by free expansion, and much of the energy expended in compression being recovered; the cooled and expanded air is used as the counter current in the regenerative coolers, and is then again compressed. When the temperature of the high-pressure air, issuing from the final refrigerator, is reduced

by the regenerative process, until the gas is almost free from oil and water vapour and partially freed from carbon dioxide (perhaps at -50° C.), it is sent to the liquefier, and in this the current is divided between several tubes of small diameter, enclosed in a double-jacketed spiral, and, after passing down a central spiral, the gas is allowed to expand freely, in two stages, passing from a central high-pressure chamber in the lower part of the liquefier, into a surrounding chamber at intermediate pressure, and then into a third chamber enclosing the second, in which the pressure is reduced almost to the normal. Inner and outer regenerative jackets enclosing the spirals, communicate with the intermediate and low-pressure chambers respectively. Some of the air is liquefied in the process of expansion, and the rest passes out through the external regenerative coolers, as counter-current. In order to make use of the apparatus for the separation of air into oxygen and nitrogen, liquid air is allowed to accumulate in the expansion chambers of the liquefier; the liquid in the intermediate chamber then continuously evaporating by absorbing heat from the inner high-pressure chamber, gives a gas consisting almost entirely of the more volatile nitrogen, and the product passing into the outer chamber is sufficiently rich in oxygen to give the commercially pure gas by its continual evaporation in that chamber. The apparatus is suitable for dealing, not only with air, but with any gas or gaseous mixture having a critical temperature below -18° C.

VIII.—GLASS, POTTERY, AND ENAMELS.

PATENTS.

Glass; Process for annealing and hardening — J. F. Farling, Bluffton, Ind. U.S. Pat. 928,860, July 20, 1909.

GLASS is submerged in an aqueous solution of saltpetre, common salt, and "wood-lye," which is heated to boiling, after which the glass is packed between a mixture of slaked lime, chloride of lime, salt, saltpetre, and powdered alum, and subjected to the action of dry heat. After cooling, the glass is finally cleansed by means of dilute sulphuric acid.—O. R.

Earthenware articles; Process of manufacturing lavatory-basins or other — J. Clifford, Chicago, Ill., and C. Weedans, Trenton, N.J. Assignors to Monument Pottery Co., Trenton, N.J. U.S. Pat. 929,390, July 27, 1909.

A SOLUTION of potassium silicate, or of potassium silicate and carbonate, is thoroughly incorporated with the clay mixture, which is poured into plaster of Paris moulds, until the latter are full. After the mixture has settled down in the moulds, owing to the absorption of water by them, the pouring operation is repeated, and the mixture is allowed to set and harden in the moulds, until of sufficient strength to permit of its removal without injury.—W. C. H.

Tiles; Machine for coating flooring or ornamental — and similar products, The Ceramic Machinery Co. Fr. Pat. 399,269, Feb. 9, 1909.

SEE Eng. Pat. 3139 of 1909; this J., 1909, 796.—T. F. B.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Blast furnace slags; Experiments to test the influence of chemical composition on the hydraulicity of — H. Passow, Stahl und Eisen, 1909, 29, 1267-1273.

THE several constituents of blast furnace slag were fused together in various proportions in a graphite crucible, and the molten mixture was poured into cold water, so as to obtain as glassy a product as possible. To the finely ground material was added 10 per cent. of a cement, prepared by clinkering a mixture of limestone and blast furnace slag. These mixtures were then briquetted with 3 times their weights of standard sand, and tested for tensile strength after different periods in air, under fresh water, and under sea water. The author concluded that: (1), glassy slags had no cementitious properties *per se*, but would only set hard in conjunction with lime, or with substances capable of yielding lime; (2), a slag containing less than 50 per cent. of bases was of very little value as a basis for cement; (3), the cementitious value of a slag was dependent, not only on a high proportion of bases, but also on the ratio of the amount of bases to the amount of silica contained, a high proportion of silica and a low proportion of alumina being, within certain limits, prejudicial to the cementitious value; (4), The presence of magnesia up to 13 per cent. in glassy slags often increased the cementitious value of such slags without being in any way deleterious; (5), the presence of calcium sulphide up to 12 per cent. likewise increased the cementitious value without injury to the product; (6), calcium sulphide up to 12 per cent., in the presence of 5 per cent. of magnesia, had no harmful effect; (7), all the trial mixtures that possessed cementitious properties, attained a greater degree of strength and hardness under sea water than under fresh water.—O. R.

PATENTS.

Self-filling composition, C. L. Norton, Manchester, Mass., U.S.A. U.S. Pats. 929,002, 929,003, and 929,004, July 27, 1909.

(1). THE composition consists of 20 parts by weight of "asbestiform fibres," 10 to 12 parts of hydraulic cement,

and 50 parts of water, this proportion of water being insufficient to produce mobility of the fibres in the mixture. (2). The composition consists of 1 part by weight of magnesium oxide, 2½ to 3 parts of asbestiform fibre, and 6 to 7 parts of water, this amount of water being insufficient to allow the fibres to be motile in the mixture. (3). The process consists in compressing a mass comprising fibres, cementing material, and a setting liquid. Portions of the foundation fibres in the mass are felted into self-sustaining filtration webs and only those portions of the material which lie between the webs are supported. By compression, the surplus liquid is expressed through the webs, whilst the cementing material is retained on them.—W. C. H.

Aluminous material; Method of treating — A. C. Higgins, Worcester, Mass., U.S.A. U.S. Pat. 929,219, July 27, 1909.

ALUMINOUS material is fused in an electric furnace at a temperature well above the state of quiet fusion, and sufficient to prevent substantial segregation of impurities. The resulting product is then cooled or chilled into a pig or solid mass.—W. C. H.

Cement and the like; Process and apparatus for burning — B. E. Eldred, Bronxville, N.Y., Assignor to The Eldred and Palmer Co., New York. U.S. Pat. 928,512, July 20, 1909.

IS a rotary kiln, a travelling stream of powdered cement material is calcined by means of a mixture of burning gas, its products of combustion, and air, in definite proportions, and is then clinkered by a separate source of heat.—O. R.

Cement; Process and apparatus for burning — B. E. Eldred, Bronxville, N.Y., Assignor to The Eldred and Palmer Co., New York. U.S. Pat. 928,513, July 20, 1909.

CALCINED cement material, at or near the clinkering temperature, is introduced into the upper end of a closed rotary kiln. Burning is effected by means of a jet of powdered coal, which is fed into the lower end of the kiln, a pair of regenerators being provided, with flues opening into the lower end of the kiln, on either side of the coal jet. Means are provided for alternately passing the waste gases of the kiln and the air used for producing the coal jet, through each of the regenerators.—O. R.

Cement; (1) Apparatus for making, (2) Process of making — R. W. Lesley, Haverford, and H. S. Spaekman, Ardmore, Pa., Assignors to Pine Street Patents Co., New Jersey. (1) U.S. Pat. 929,144, and (2) 929,145, July 27, 1909.

RAW cement material is coarsely crushed, and continuously fed into a rotary calcining kiln, provided with an independent fuel supply, in which carbon dioxide is expelled from the raw materials. The air supplied for supporting combustion in this kiln is pre-heated by contact with the calcined material discharged from the kiln. Means are provided for finely grinding and mixing the calcined material, and for continuously feeding the finely ground mixture into a clinkering kiln, heated to the clinkering temperature by producer gas. The clinker is passed into a rotary cooler, which serves to preheat the air supplied for combustion in the clinkering kiln. The flame in this kiln travels in the opposite direction to the feed of the material which is being clinkered. The plant is arranged so that the material is continuously passed through the different stages of the process by mechanical means.—W. C. H.

Artificial stone, mortar, plaster, and the like; Process for rendering — waterproof, heat and electricity non-conducting, and soundproof. J. Kathe, Cologne, Germany. Eng. Pat. 15,100, July 16, 1908.

SEE Fr. Pat. 396,486 of 1908; this J., 1909, 602.—T. F. B.

X.—METALS AND METALLURGY.

Copper smelting; High silica slags in Mexican —. C. A. Heberlein. Eng. and Min. J., 1909, 88, 107—108.

AN account is given of the blowing in of a new water-jacketed smelter at Magistral, Mexico, together with a table of analyses of the slags obtained during the first month. The charge consisted of ore, iron ore and lime, and the consumption of fuel, which at the commencement was 12 per cent. per ton of charge, was reduced during the run to 8.1 per cent., equivalent to 6.96 per cent. of fixed carbon, with an average of 7.5 per cent. of sulphur in the charge. The slag produced is essentially a bisilicate slag having an average composition of 50 per cent. of silica, 22 per cent. of lime, 20.5 per cent. of ferrous oxide, and 4.5 per cent. of alumina, the copper content being about 0.22 per cent. In the presence of this large amount of silica, the alumina undoubtedly acts as a strong base, and the author believes, from his experience at the Copper Queen on slags as high as 32 per cent. of alumina, that, contrary to C. E. Shelby (see this J., 1908, 903), alumina in slags always acts as a base. Comparative analyses of Magistral and Mansfeld slags are given.—F. R.

Aluminium; Analysis of —; *Direct determination of metallic aluminium*. E. Kohn-Abrest. Ann. Chim. anal., 1909, 14, 285—289.

IN order to determine directly the percentage of aluminium volatilised as chloride (i.e., the metallic aluminium present) by the method already given for the analysis of the commercial metal (this J., 1909, 839), special precautions must be taken to condense the whole of the chloride vapour and to effect its solution in water without loss. The author describes an apparatus, in which this is conveniently carried out. The tube shown is 75 cm. long and 1.6 cm. in diameter; at one end it communicates by a two-way tap with a source of pure dry hydrogen, which is freed from oxygen by passage over heated copper, and with an apparatus for generating pure dry hydrogen chloride; at the other end of the tube is attached the receiver, B, of about 500 c.c. capacity; the exit tube from this communicates with a second vessel, each tubulure of which is furnished with a tap, and this is connected to a wash-bottle containing sulphuric acid. The tube is heated, 7—8 cm. from the anterior end, over 15 cm. of its length, the thermometer being placed outside the tube. After drying the apparatus, the sample of aluminium is introduced into the heated part of the tube in a shallow porcelain boat, and the heating in hydrogen and hydrogen chloride is carried out as described (*loc. cit.*), a fairly rapid current of hydrogen chloride being used. At first the reservoir is cooled by water, but most of the chloride condenses in the tube itself. When the attack is complete, the boat is allowed to cool in a current of hydrogen, and is then withdrawn and weighed, chlorine and iron being determined in the residue. In order to dissolve the sublimed aluminium chloride, a bulb tube, containing water, is attached to the anterior end of the combustion tube, and a partial vacuum is produced in the vessel connected with the receiver, by means of a filter pump; water is then sucked into the apparatus by closing the tap between this vessel and the pump, and opening that between it and the receiver. The solution and rinsings are made up to a known volume, and the chlorine determined volumetrically with silver nitrate, the corresponding quantity of aluminium being then calculated; iron is also determined, if present in appreciable quantity, and a correction made, 1 of chlorine corresponding to 0.5290 of iron and to 0.2535 of aluminium.

The method may be used also for the determination of aluminium in its alloys with many metals, such as indium, cadmium, zinc, magnesium, glaucinum, cerium, thorium, barium, calcium, copper, lithium, sodium, potassium, iron, and chromium.—F. SOHN.

Silicides of the alkaline earth metals. O. Hönigschmid. Monatsh. f. Chem., 1909, 30, 497—508.

CRUDE silicides of calcium, barium and magnesium, obtained by Goldschmidt's process (see this J., 1908, 948) and suitable for use in place of aluminium in certain thermite reactions, were examined and found to consist of definite silicides of the earth metal in admixture with iron silicide and free silicon. Two crude silicides of calcium were examined. One, prepared with excess of silicon, contained the silicide, CaSi_2 , whilst the other, prepared with excess of calcium, contained Hackspill's silicide, Ca_3Si_2 (this J., 1908, 684), and was free from the lower silicide, CaSi_2 . In the case of barium and of magnesium, one silicide only is formed, having the formula, BaSi_2 or Mg_2Si .—A. T. L.

Silicone. O. Hönigschmid. Monatsh. f. Chem., 1909, 30, 509—525.

"SILICONE," a compound containing silicon, hydrogen and oxygen obtained by Wöhler by dissolving calcium silicide, CaSi_2 , in strong hydrochloric acid, was analysed and found to have the formula, $\text{Si}_2\text{H}_3\text{O}_2$. On heating "silicone" *in vacuo*, or in a current of hydrogen, the whole of the hydrogen is liberated, and a greyish black substance is left. The hydrogen in "silicone" is therefore probably attached to the silicon and not to the oxygen atoms. The greyish black substance is probably the suboxide, Si_2O_2 , analogous with Dicks' carbon suboxide, C_2O_2 . It dissolves in potassium hydroxide solution, and in hydrofluoric acid, with evolution of hydrogen. On heating the suboxide to 400° C. in chlorine or in hydrochloric acid, silicon tetrachloride and silica are formed. Wöhler's "leucone," a white substance formed by leaving the dark yellow "silicone" in air or in the presence of water, was found to have the formula, $\text{Si}_2\text{H}_3\text{O}_4$. It is not the final product of atmospheric oxidation. When heated *in vacuo*, "leucone" loses hydrogen, leaving a golden brown residue which has the formula of a second suboxide, Si_2O_4 .—A. T. L.

(a) Exclusive of the copper produced in the State during the year from ore imported for treatment from other States of the Commonwealth. (b) Including iron made from scrap. (c) See silver-lead. (d) Value at smelting works. (e) Value at quarries of quantity disposed of. (f) The bulk of the silver is contained in the concentrates, &c., despatched from the Broken Hill Field and treated outside the State. (g) Quantity exported only. (h) Exclusive of tin refined in the State from imported ores.

Barium compounds in the United States. See VII.

PATENTS.

Steel; Toughening — S. S. Wales, Munhall, Pa., Assignor to Carnegie Steel Co., Pittsburg, Pa. U.S. Pat. 928,347, July 20, 1909.

THE steel is heated to a temperature between 775° and 875° C., chilled by means of water, and again heated to between 500° and 650° C. It is finally quenched by "a cooling liquid."—C. A. W.

Ballistic plate. S. S. Wales, Munhall, Pa., Assignor to Carnegie Steel Co., Pittsburg, Pa. U.S. Pat. 928,348, July 20, 1909.

As a new article of manufacture a ballistic or armour steel plate is manufactured free from chromium, but containing vanadium (below one per cent.), and varying quantities of tungsten and nickel. As an instance, the composition tungsten, below one per cent.; nickel, from three to ten per cent.; vanadium, below one per cent., may be taken as typical.—C. A. W.

Ferro-silicon; Treatment of acid slags and silicious iron ores for the manufacture of — in the electric furnace. C. Bertolus. First Addition, dated Jan. 26, 1909, to Fr. Pat. 393,818 of Aug. 31, 1908.

THE slag or ore is agglomerated with silica and with sufficient carbon to completely reduce the iron and partly reduce the silica. When heated in the electric furnace the excess of silica combines with the alumina and lime, or manganese, forming a fusible silicate slag which readily separates from the ferro-silicon. Ferro-silico-aluminium is made by using an excess of reducing agent and increasing the percentage of alumina by the addition of bauxite, aluminium silicate, or the like.—F. R.

Galvanising; Method of — G. L. Patterson, T. L. Morner, and C. H. Zieme, New Castle, Pa. U.S. Pat. 928,398, July 20, 1909.

THE zinc in the form of flue-dust is incorporated with finely divided clay in a suitable liquid, finely divided carbon being added, so that an inert and chemically non-reactive vehicle, together with a reducing agent, is

obtained. The surface to be coated is dipped in the composition, and, after withdrawal, is subjected to the action of heat.—C. A. W.

Silicon nitride; Manufacture of — A. Sinding-Larsen, Christiania. U.S. Pat. 928,476, July 20, 1909.

IN a chamber, which forms part of, or which is connected with, an electric furnace, silicon vapour or finely divided silicon is heated in the presence of an atmosphere consisting chiefly of nitrogen.—O. R.

Ores, mattes, etc., containing sulphur; Preliminary treatment of — previous to smelting. J. Savelsberg. Fr. Pat. 399,101, Feb. 3, 1909.

ORES, mattes, etc., containing sulphur are crushed to about 2–3 mm. diameter, and mixed with sufficient sand, or ores containing silica, to form ferruginous silicates. The mixture is agglomerated by being moistened and then strongly heated in a furnace through which a current of air passes; part of the sulphur burns off, and part combines with the copper or other metals, the iron being completely converted into oxide.

(See also this J., 1908, 128, for process for ores free from sulphur.)—F. R.

Zinc blende; Separation of — from other metalliferous constituents, in concentrates, &c. E. J. Horwood. Fr. Pat. 399,272, Feb. 9, 1909.

COMPLEX lead-zinc ores are first concentrated by an oil or other flotation process, and the concentrates heated to 300° C. to 400° C., or they are digested in a suitable acid bath, with or without heat, for the purpose of partially sulphating the galena, the zinc blende being practically unaltered by the treatment. The treated concentrates are again concentrated by the previous process when it is found that the particles of galena, coated with lead sulphate, no longer float, thus enabling the unaltered blende to be readily separated.—F. R.

Gold; Process for the precipitation of — from solutions, and for the decolorisation of solutions of sugar or other substances. H. Hay and B. E. Tennent. Fr. Pat. 399,877, Feb. 24, 1909.

THE property that charcoal possesses of precipitating gold from solution, is said to be due to the presence of hydrogen

carbonyl in the charcoal; the object of this patent is to increase the quantity of hydrogen carbonyl, by heating wood charcoal in a muffle or retort to between 700° and 1400° C., and passing steam over it. When cool the charcoal is said to be capable of precipitating 20 times the amount of gold from solution that untreated charcoal can. The treatment also improves the efficiency of the charcoal for the removal of vegetable colouring matter from solutions of sugar or other substances.—F. R.

Steel and iron; Process for the treatment of —. W. P. Thompson, Liverpool. From William Sauntry Metals Co., Portland, Maine, U.S.A. Eng. Pat. 16,552, Aug. 5, 1908.

SEE Fr. Pat. 393,452 of 1908; this J., 1909, 145.—T. F. B.

Cemented armour plates of steel and alloys of steel, for ships and other uses; Manufacture of —. E. C. R. Marks, London. From Soc. anon. Italiano Gio. Ansaldo Armstrong Co., Genoa, Italy. Eng. Pat. 16,806, Aug. 10, 1908.

SEE Fr. Pat. 393,355 of 1908; this J., 1909, 145.—T. F. B.

Armour plates and other articles of steel or alloys of steel for ships and other uses; Manufacture of —. E. C. R. Marks, London. From Soc. Anon. Italiano Gio. Ansaldo Armstrong Co., Genoa, Italy. Eng. Pat. 16,972, Aug. 12, 1908.

SEE Fr. Pat. 393,355 of 1908; this J., 1909, 145.—T. F. B.

Iron; Process for the direct extraction of — from ores. W. S. Simpson and H. Oviatt. Fr. Pat. 399,901, Feb. 5, 1909. Under Int. Conv., Nov. 16, 1908.

SEE U.S. Pat. 918,381 of 1909; this J., 1909, 527.—T. F. B.

Steel; Process for making — direct from the ore. W. S. Simpson and H. Oviatt. Fr. Pat. 399,902, Feb. 5, 1909. Under Int. Conv., Nov. 16, 1908.

SEE U.S. Pat. 918,382 of 1909; this J., 1909, 527.—T. F. B.

Magnesium and alloys thereof; Melting and casting —. G. W. Johnson, London. From Chem. Fabr. Griesheim Elektron, Frankfurt, Germany. Eng. Pat. 15,038, July 15, 1908.

SEE Fr. Pat. 393,080 of 1908; this J., 1909, 27.—T. F. B.

Minerals of any kind; Process and apparatus for the treatment of — for the purpose of extracting the metal they contain. B. Junquera, Santa Susana, Spain. Eng. Pat. 21,921, Oct. 16, 1908.

SEE Fr. Pat. 394,719 of 1908; this J., 1909, 370.—T. F. B.

Crucible furnaces. A. J. Boulton, London. From Kroeschell Bros. Co., Chicago, U.S.A. Eng. Pat. 1786, Jan. 25, 1909.

SEE U.S. Pat. 910,091 and 911,271 of 1909; this J., 1909, 207, 247.—T. F. B.

Silicon nitride; Process of making —. A. Sinding-Larsen and O. J. Storm. Fr. Pat. 399,445, Feb. 13, 1909. Under Int. Conv., Feb. 17, 1908.

SEE U.S. Pat. 928,476 of 1909; preceding.—T. F. B.

Zinc ores; Treatment of — by a preliminary fusion followed by precipitation of the metal by molten iron. Imbert Process Co. Fr. Pat. 399,854, May 5, 1908.

SEE Eng. Pat. 13,492 of 1908; this J., 1909, 144.—T. F. B.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

PATENTS.

Electric arcs in series; Impts. relating to the working of —. H. Pauling, Gelsenkirchen, Germany. Eng. Pat. 6429, March 17, 1909.

THE electric arcs are arranged in series with the main working circuit, and a high pressure auxiliary arc-striking

circuit, provided with an ohmic or inductive resistance, is connected in parallel with all but one of the arcs. The auxiliary circuit may be provided with a high pressure generator independent of the main generator, or may be supplied with current from the secondary coil of a transformer, the primary being arranged as a shunt with the main working circuit.—B. N.

Diaphragm; Electrolytic — and method of making same. A. G. Betts, Troy, N.Y. U.S. Pat. 929,276, July 27, 1909.

AN asbestos board diaphragm for use in aqueous electrolysis is prepared by cementing together the fibres in an asbestos board with an easily fusible substance that is insoluble in the solution to be used. For example, powdered sulphur is dusted on to the surface of the board, and the latter heated until the sulphur fuses.

—F. R.

Electrolytic cell. J. McPhail, Assignor to W. J. Burke and H. R. Nelson, Carteret, N.J. U.S. Pat. 929,469, July 27, 1909.

THE cell consists of a rectangular containing vessel, having internal brackets or ledges at opposite ends, to support an inner vessel of U-shaped cross section, composed of wire netting lined with a fibrous material to act as a diaphragm. The inner vessel is furnished with slate ends, adapted to fit into the brackets of the outer vessel.—F. R.

Water; Apparatus for the electrolysis of —, with platinum electrodes. J. Greil. Fr. Pat. 399,279, Feb. 9, 1909.

A NUMBER of tubes are suspended vertically in an outer vessel containing the acidulated water to be electrolysed. Each tube contains a thin platinum sheet, extending nearly to the bottom of the tube, the upper end of the latter being closed but permitting electrical contact with the platinum plate. The tubes are all of the same length, but those containing negative electrodes, in which the hydrogen is collected, have double the capacity of the others, so that the level of the electrolyte decreases equally in each tube.—F. R.

Electrodes for accumulators. H. J. Haddan, London. From Nya Akkumulator Aktiebolaget Jungner, Fliscryd, Sweden. Eng. Pat. 21,004, Oct. 5, 1908.

SEE Fr. Pat. 395,138 of 1908; this J., 1909, 315.—T. F. B.

Wool scouring by electricity. Fr. Pat. 399,875, Feb. 24, 1909. See V.

(B.)—ELECTRO-METALLURGY.

Metals; Corrosion of — underground by electrolysis. A. A. Knudson. J. Franklin Inst., 1909, 168, 132—152.

THE object of the paper is to set forth the present position of electrolytic action upon subsurface metals, due to railway currents. In the single trolley system which, with the exception of the double underground trolley at New York and Washington, is in general use in America, the current is carried to the cars by a single overhead wire, reinforced by copper feeders, the return current being theoretically conveyed to the power house by the rails. As the rails are "grounded," the return current becomes divided and a portion flows along such water or gas mains as the damp soil, acting as a conductor, brings within range, the amount transmitted being in inverse ratio to their several resistances. Though the condition of the track, therefore, has much to do with the proportion of current leaving it, yet with 90 or 100 lb. rails, well bonded and with suitable auxiliary copper feeders, some current will return by indirect paths underground. At New York, part of the current flowing over the Brooklyn Bridge used to return by a number of different channels, crossing the river in various places, some as far as two miles away, but when the Williamsburg bridge was built, most of the stray currents were practically short-circuited by the mass of metal and are now conveyed by it back to the power station in Brooklyn. A test for current flow

upon one of the paths of the current, a 6 in. water pipe, coming down from the bridge, showed a maximum of 70 amperes passing through it into the water mains. The identity of these currents with those of the railway, is confirmed by systematic observations of their variation of potential, which is found to be governed by the strength of the railway current; the variations of the latter caused, for instance, by the press of traffic between 5 and 7 o'clock in the evening, is faithfully reproduced in detail by the current flowing through the water mains, as is shown by comparative curves. The most destructive effect of electrolysis is shown where the current passes out from a main to another conductor, resulting in the well-known "putting" and eventual perforation of the metal, but damage is also caused to the joints of the pipes by the current passing along them, the inside of the joint being chiefly affected by the electrolytic action. The author describes and illustrates a number of cases of corrosion, including that of water meters, but though he considers that the damage may be lessened by improved track returns, he believes that the only remedy lies in a non-grounded return.—F. R.

PATENTS.

Furnaces; Electric — for the treatment of ores and the like. B. E. D. Kilburn, London. From E. Oesterle, Muncie, Indiana, U.S.A. Eng. Pat. 15,645, July 23, 1908.

THE furnace comprises a hollow circular floor or hearth surrounded by an annular chamber having water-jacketed walls, the lower inner edge of the walls forming a circular lip just above the level of the molten metal on the hearth. A gas, such as carbon monoxide, preferably heated, is forced through openings in the top of the annular chamber, and down through the ore contained in it, issuing from under the circular lip and acting upon the surface of the molten metal.—B. N.

Aluminium ores; Treatment of — and aluminium silicate ores. F. J. Tone, Assignor to the Carborundum Co., Niagara Falls, N.Y. U.S. Pats. 929,517 and 929,518, July 27, 1909.

A MIXTURE of aluminium silicate and emery is mixed with sufficient carbon to reduce the silica and all other compounds except alumina, and is placed as a resistance conductor between the electrodes of an electric furnace. It is then heated to the fusing point, but not the reduction temperature of alumina, and the fused alumina separated from the reduction products.—F. R.

Iron and steel and other metals; Electric production of —, and furnaces for carrying out the same. Aktiebolaget Elektrometall, Stockholm, Sweden. Eng. Pat. 6088, March 13, 1909. Under Int. Conv., Aug. 1, 1908.

THE furnace consists of a smelting chamber, with two adjustable electrodes or groups of electrodes hanging in the chamber from the cover, so that the current passes in the form of arcs to the smelting bath. Each electrode or group is connected with one of the terminals of one pole of a two-phase alternating current system, the terminals of the other pole being connected with a fixed electrode or group of electrodes arranged in the bottom of the chamber. The latter electrode or electrodes may be formed either wholly or partly of a lining of magnesite, dolomite, or the like, wholly or partly surrounded by or arranged on a mass, such as graphite, which acts as an insulator against heat, but at the same time is, even when cold, a conductor of the electric current; or the lining of magnesite, etc., may be mixed with pitch, tar, or the like.—B. N.

Electroplating plant. W. R. King, Newark, N.J., Assignor to the Hanson and Van Winkle Co., N.J. U.S. Pat. 929,312, July 27, 1909.

FOR electroplating long lengths of metallic material, such as wire or ribbon, the material passes from a drum or reel, on which it is wound, continuously and successively into a heated metallic potash-tank, which is connected to one pole of an electric circuit, over a contact rod

connected to the other pole of the circuit, through a cold water tank, a pickling bath, a second cold water tank, over a second contact rod, through a copper-bath tank connected to the other pole by contact rods from which anodes are suspended adjacent to the upper and under sides of the material to be plated, through a third cold water tank, an electroplating tank with electric connections similar to the previous tanks, finally through a hot water tank and a drying chamber and is collected on a drum or reel. The tanks are furnished with internally arranged guide rolls.—F. R.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Whale oil industry in Natal. Board of Trade J., Aug. 19, 1909. [T.R.]

THE whaling company which has been working from Durban during the last two years has now completed the erection of a new factory and plant, and expects to increase the production of oil very largely during the present season. 106 whales were taken during the latter part of last season. Arrangements have been made to manufacture fertilisers from the residue of the carcass of the whale, new works having been erected at a cost of nearly £15,000 for this purpose.

Soaps and oils in Turkey. Board of Trade J., Aug. 19, 1909. [T.R.]

THERE is a growing demand for yellow bar and fancy toilet soaps of all descriptions, preferably of the cheaper kinds. The annual decrease of the olive crop and the increased demand for olive oil for food leaves little native oil for soap making. The objection to using animal fat makes it necessary to resort to vegetable oils. Experiments are being made with corn (maize) oil from the United States and with linseed oil from the United Kingdom; 800 barrels of the former and 700 of the latter were imported in 1908. If these are found satisfactory there is likely to be a large demand for them in future.

PATENTS.

Oil; Means for purifying waste —. C. A. J. Albert, Kvillebäcksvägen, Sweden. U.S. Pat. 929,266, July 27, 1909.

THE apparatus consists of a tank divided into upper, middle, and lower compartments. The oil is supplied to a box in the upper chamber; this box contains a filter and wicks are provided for feeding the oil from the box into the upper chamber. Filters are placed in each chamber and a pipe reaches from the upper to the lower chamber. The oil is heated while it is in the upper and lower chambers, and in the latter the oil is brought into contact with a solution of common salt. Means are provided for distributing the oil from the middle chamber.—W. P. S.

Saturated compounds from solid or nearly solid unsaturated fatty acids or their esters; Process for preparing — by hydrogenation in presence of nickel. E. Erdmann. Ger. Pat. 211,669, Jan. 19, 1907.

SOLID or semi-solid, unsaturated acids or esters are converted into saturated compounds by introducing them, in the form of powder or fine drops, together with hydrogen, into a vessel containing finely divided, heated nickel. The nickel may be deposited on asbestos or other suitable substance. Oleic acid is quantitatively converted into stearic acid, and linoleic and linolenic acids are also readily hydrogenated. For example, oleic acid is sprayed, by means of compressed hydrogen, on a rotating tube of earthenware impregnated with reduced nickel, which is placed within a closed nickel cylinder, the apparatus being heated to 180° C. The stearic acid is finally passed through a layer of pumice impregnated with nickel.

—T. F. B.

Hydroxychlorofatty acids and their glycerides; Process for preparing — by the action of hypochlorous acid on fatty acids and their glycerides. Consortium I. Elektrochem. Industrie, and G. Imbert. Ger. Pat. 212,001, Jan. 6, 1907.

FATTY acids and their glycerides may be converted into hydroxylated and chlorinated fatty acids by treatment with an aqueous solution of alkali hydroxide saturated with chlorine, but a large excess of this solution is necessary. If alkali carbonates or bicarbonates are used in place of hydroxides, the excess required does not exceed 10 per cent., and the reaction proceeds equally well. For example, 329 kilos. of oleine (iodine value 86) and 123 kilos. of calcined soda are dissolved in 1600 litres of water, and 87.5 kilos. of chlorine are passed into the solution; a thick, white, creamy emulsion is thus produced, from which the free acid may be precipitated by addition of the calculated quantity of dilute sulphuric acid.—T. F. B.

Oil from oleaginous materials such as seed; Process of and apparatus for extracting —. P. M. Justice, London. From J. E. Mills, Chapel Hill, N.C., and H. B. Battle, Montgomery, Ala., U.S.A. Eng. Pat. 15,500, Jan. 21, 1909.

SEE U.S. Pat. 913,751 of 1909; this J., 1909, 373.—T. F. B.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(B.)—RESINS, VARNISHES.

Turpentine oil; Fractional distillation of — in a current of steam. W. C. Geer. Chem.-Zeit., 1909, 33, 859.

Fig. 1.

Fig. 2.

WITH the aid of the distillation tube here illustrated it is possible to effect an almost complete separation of the constituents of an oil of turpentine. The apparatus consists of a glass tube about 3 cm. in diameter, provided at regular intervals with constrictions of different diameter, the smallest being at the bottom and the largest at the top. In each of these constrictions is placed a V-shaped tube filled with water, and having at the top a collar of wire gauze. On distilling a turpentine oil which consists in the main of a single constituent, the temperature of the steam leaving this tube remains almost constant, whereas a sudden rise of temperature takes place when other constituents begin to distil. The use of this apparatus also obviates the risk of altering the composition of an oil of turpentine by too high a temperature. Analyses are given of the 10 to 12 fractions thus obtained in the distillation of a sample of ordinary turpentine, and of three samples of wood turpentine. Tables are also given.

—C. A. M.

Report of Principal Chemist of the Government Laboratory for the year ended 31st March, 1909. See XVII.

(C.)—INDIA-RUBBER, &c.

Rubber samples from German E. Africa. Gummi Zeit., 1909, 23, 1464. From Der Pflanzer, 1909, 5, No. 2.

THE samples were some sent for exhibition at the Rubber Exhibition, Olympia, 1908, and were examined and valued in the laboratory of the "Vereinigte Gummiwaren-Fabriken Harburg-Wien." The following results were obtained:—

Sample No.	Botanical origin.	Loss on washing	Resin. Wax.			Ash. M.p.	
		per cent.	per cent.	per cent.	per cent.	°C.	
1	Manihot Glaziovii	0.00	5.8	5.2	1.22	140	
1c	"	0.00	6.5	3.5	1.42	145	
2A	"	0.00	6.8	7.4	1.40	140	
18	Laudolphia Kirkii	3.20	3.1	1.9	0.42	145	
22	Manihot Glaziovii	11.20	9.3	4.8	3.40	140	
23	"	32.00	6.8	4.3	2.48	150	
25	"	28.90	9.3	5.0	1.70	130	
26	"	27.30	1.07	3.8	1.84	130	
27	"	10.00	6.6	5.8	2.48	150	
28	"	19.20	6.3	4.9	2.02	145	

Samples 1 and 1c were from 3½-year-old trees grown in Anani at 850 metres; latex coagulated on tree trunk, and rubber washed. Sample 2A from 2½-year-old trees grown at 450 metres, coagulation, &c., as in sample 1. Sample 18, collected by natives. Sample 22, was coagulated on the tree, and the crude rubber smoked. Sample 23 was from 4-year-old trees in the Muanza district. Samples 25–27 were coagulated on the tree, sample 26 being afterwards washed with 2.5 per cent. acetic acid, and sample 27 smoked. Sample 28 was from 2½-year-old trees in the Morogoro district.—E. W. L.

Rubber; Production of — from the latex of Kickxia cluscia. C. Kinkelbach and A. Zimmermann. Gummi Zeit., 1909, 23, 1464; from Der Pflanzer, 1909, 5, No. 3.

THE latex of *K. cluscia* cannot be coagulated by the method employed in the case of *Manihot* (viz., coagulation on the tree-trunk itself), on account of the sluggishness with which the change occurs. The latex is therefore collected, and the rubber may be obtained from it by one or other of the following methods:—(1). By diluting the latex with 10 to 20 times its own volume of water, separating the aqueous liquid from the rubber cream, washing the cream with water, and finally separating the rubber by means of a filter-press. (2). By the use of "Purub" [a solution of hydrofluoric acid—see this J., 1908, 1029, 1074]. The use of this coagulant does not appear to be attended by any distinct advantages, though experiments with it were not extensive, owing to lack of material. (3). By simple dilution with water. Further experiments are, however, necessary before it can be definitely decided whether this method is suitable for use on the large scale.—E. W. L.

Rubber; Determination of — in raw rubber, as tetrabromide. C. Harries and H. Rimpel. Gummi Zeit., 1909, 23, 1370–1371.

THE authors have compared the results obtained by Bidde's later method of rubber estimation (see this J., 1907, 1057) with those obtained for the same samples by means of the nitrosite method (Harries, this J., 1901, 1123; 1902, 1404; 1903, 103; 1908, 81; also Gummi-Zeit., 1907, 21, 1205). Determinations were also made with samples of highly purified Para rubber, prepared by triple precipitation from benzol solution.

combined with alternate extraction with acetone for 24 hours (see Harries, this J., 1905, 448, and Ber., 1905, 38, 1198). The results are given in the following table:—

Kind of rubber.	Rubber-content.	
	Nitrosite method.	Bromide method.
	Per cent.	Per cent.
Gaayule (crude)	88.8	76.2
Ceylon Para (sheeted)	96.0	88.8
Congo (Equateur, crude)	92.09	85.3
Para, chemically pure	101.8	86.1
" " "	99.47	91.8

It was observed that in carrying out the bromide process, hydrobromic acid was invariably produced, indicating either that some substitution occurs, or that hydrogen bromide is eliminated in the following way:—

The insoluble bromination product is without doubt a tetrabromide, $\text{C}_{16}\text{H}_{16}\text{Br}_4$, but the authors find that a product containing a higher percentage of bromine passes into the filtrate, being soluble in a mixture of two parts of carbon tetrachloride with one part of alcohol. This product was isolated by carefully evaporating the filtrate in a vacuum at 20° – 30° C., when a red oil, interspersed with crystals, and which gave off hydrobromic acid when exposed to the air, remained behind. On leaving this in a vacuum over sulphuric acid and caustic potash, a dark brown solid was obtained. This was purified by precipitation from its solution in carbon bisulphide with petroleum ether. When the percentage of rubber, calculated from the weight of the soluble product on the assumption that it is a tetrabromide, was added to the percentage calculated from the insoluble product, the sum was, in every case examined, greater than 100. The soluble product amounted in three instances to 8, 10, and 15.3 per cent. respectively, calculated as rubber in the original sample. In its present form, therefore, the Budde method does not give reliable results.—E. W. L.

Rubber; Plantation v. wild —, "Times," Sept. 1, 1909. [T.R.]

THE quality of plantation rubber has recently been the subject of complaint. In standard works it is stated that plantation rubber will not keep more than six months; at the end of that time it will be full of bacteria, whilst wild rubber improves with keeping. It is evident that this is now appreciated by manufacturers, as the price of the Amazon wild rubber (containing 15 per cent. of water) has for a considerable period fetched only 3d. below plantation rubber (with under 5 per cent. of water). This margin has disappeared; for the first time hard fine rubber, with its high percentage of water, has fetched more than plantation fine, and where resiliency is desirable, such as motor tyres, the demand is for wild rubber. The faults with wild rubber are not in the rubber itself, but difficulties in working, which wild rubber companies have experienced. The chief of these difficulties is that of transport. In transport over the Andes to the Pacific ports a quantity is lost owing to the mortality amongst the moles which carry it. Through the want of adequate labour many rubber companies have failed.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Clarification of tanning extracts; Valuation of dark blood albumin for the —. J. Jedlicka, Gerber, 1909, 35, 211.

The author records the determinations he usually makes in estimating the value of blood albumin samples, and gives the methods by which he operates. (1) The estimation of moisture may be carried out in two ways. About 2 grams of albumin are dried for 6 hours at 100° C., and the loss in weight noted. A greater or less time in drying results in inconstant results. Usually 9–12 per cent. of moisture is found. Estimation may also be made by distillation with petroleum. From 20–25 grms. of albumin are distilled for about $\frac{1}{2}$ hour with 50 c.c. of petroleum until 15–20 c.c. of distillate are obtained. Comparative experiments gave the following results:

Experiment.	Gravimetric method.	Distillation method.
	per cent.	per cent.
(1)	9.1	9.3, 9.6
(2)	11.0	11.3
(3)	10.1	10.6
(4)	8.5	8.2
(5)	8.9	8.8

(2) Estimation of mineral ash is made by ignition at a low temperature. About half the residue consists usually of alkali chlorides. The author has observed here two classes of albumins, one giving 2.5 to 3.5 per cent., and the other giving 5.5 to 6.5 per cent. of ash. (3) Estimation of insoluble matter is brought about by washing 5 grams of blood albumin by decantation, using 500 c.c. of water and completing the operation in one day. The residue is dried on a tared filter paper at 100° C. The drying may be hastened and oxidation prevented by washing finally with ether or acetone. The ease of solution of the soluble portion is a valuable criterion of the sample to the extract manufacturer. The "insolubles" vary between 5.4 and 20.7 per cent. on the dry albumin, but are usually from 8 to 9 per cent. (4) Estimation of the decolorising power of the insolubles is considered a criterion of the value of blood albumin. Small decolorisation experiments are carried out with two infusions, one containing and the other not containing the insolubles. (5) Estimation of total nitrogen is made by the ordinary Kjeldahl process. The quantity varies between 14.3 and 15.8 per cent., reckoned on the dry albumin. A calculation of the quantity of "useful albumin" is brought about by subtracting the water, ash, and "insolubles" from 100, and adding on the "effective insolubles."

—H. G. B.

Negative adsorption, and the estimation of the swelling action of acids on hide powder and pelt. E. Stiasny. Gerber, 1909, 35, 183, and 197.

It is pointed out that the amount of adsorption of colloid bodies does not increase as the colloidal nature of these bodies is enhanced. This is illustrated by the substances which act as efficient tanning agents, these being all bodies intermediate between the crystalloids and the undoubted colloids. Crystalloids will not tan on account of the reversibility of their adsorption, and it has many times been observed that pure colloids are not adsorbed at all. In the latter case, an adsorbing agent acts on a solution of a colloid so that the solvent is taken up but not the dissolved substance, thus raising the concentration of the dissolved colloid. Such phenomena are not common

and are usually termed "negative adsorption." The author refers to the work of Herzog with chromed hide powder and formaldehyde-gelatin, and disagrees with his explanation that the negative adsorption observed with egg albumin solutions is due to the semi-permeability of the tanned exterior of the fibres. Experiments with white hide powder (untreated) show that the negative adsorption is actually greater in this case than with chromed hide powder. A solution of egg albumin containing a little chloroform was filtered many times through glass wool until quite clear. On evaporation, 10 c.c. of this solution gave a dry residue of 91.5 mgrms. Three grams of dry white hide powder (containing 13.5 per cent. of moisture) were placed in 50 c.c. of albumin solution and allowed to stand overnight. After filtering the mixture, 10 c.c. were evaporated to dryness and yielded a dry residue of 107 mgrms. As 50 c.c. of solution contain 0.4575 gm. of dry residue, and 1 c.c. of filtrate gave 0.0107 gm. of residue, and assuming that no albumin was adsorbed,—the volume of the residual solution was $0.4575 : 0.0107 = 42.76$ c.c. The original volume of the albumin solution (50 c.c.) + the moisture in the hide powder (0.406 c.c.)—the volume of the residual liquor (42.76 c.c.), gives the amount of water taken up by the hide powder (7.646 c.c.). Hence the percentage of water in the powder after the experiment is $7.646 \times 100 : (3 + 7.646) = 71.8$. A quite similar experiment with chromed hide powder (containing 12.8 per cent. of moisture) showed 61.7 per cent. of water in the powder after the experiment. Thus white hide powder shows negative adsorption to a greater extent. Confirmatory experiments were made with hide powders first wet with a known excess of water and then placed in the albumin solution. The filtrate shows then naturally a decrease in the dry residue obtained from 10 c.c., but this is only partly accounted for by the water originally added, and is therefore due partly to negative adsorption. After these experiments, the white hide powder contained 0.6 per cent. and the chromed hide powder 62.9 per cent. of water. The high results obtained in these experiments justify the assumption that no albumin has been adsorbed. The author next employed these phenomena to study the swelling action of acids. The amount of swelling was ascertained by the percentage of water taken up by the hide powder, and the amount of acid adsorbed was ascertained by titrating the residual liquor. White hide powder was thoroughly wet back by standing with a measured excess of water for one hour, and the albumin solution and standard sulphuric acid then added. After shaking three minutes the mixture was filtered. The calculation of results is similar to the case recorded. The results obtained are given in the following table:—

Sulphuric acid solution employed.	Percentage of water in swollen hide powder.	Percentage of sulphuric acid in swollen hide powder.
N/1	79.7	4.75
N/2	81.75	2.9
N/4	83.19	1.655
N/10	85.385	0.914
N/20	86.3	0.62
N 40	85.65	0.445
N/100	68.06	0.086
Water only	79.53	—

The figures are averages of duplicate or triplicate experiments which showed good concordance, especially with the more dilute solutions. It will be noted that the swelling increases with the concentration of the acid, attains a maximum, and then decreases again. The difference between the swelling obtained with acid solutions and with water only is not so striking as was expected. With regard to the acid adsorbed, it is shown that relatively more is taken up from the more dilute solutions, at the experiment with N/100 acid is a notable exception. The author next investigated whether these results hold good with actual pelt. A glass vessel of 250 c.c. capacity was employed, the ground glass stopper of which had a glass cap on which to place the platinum wire that held the pelt. About 20 grams of pelt were suspended thus in water for some hours and then weighed. This gave the

normal weight of wet pelt. The piece was next suspended in the acid solution for four hours and again weighed. This weight—less the normal pelt weight—gave the water and acid content (a). Titration of the residual liquor showed the amount of acid adsorbed (b), and hence (a)—(b) is the water content, i.e. the swelling. The pelt was a strip taken from the middle of a butt, and as constant as possible throughout its substance. It was stored in chloroform water covered with a layer of toluene and in a cool chamber. The results obtained in these experiments are shown herewith:—

Concentration of acid solution.	Grams of water taken up by 1 gram of pelt.	Grams of acid taken up by 1 gram of pelt.
Sulphuric acid.		
4N	-0.4219	0.4850
3N	-0.1239	0.1483
2N	-0.0145	0.0571

$\frac{1}{4}$ N	0.0452	0.0102
$\frac{1}{5}$ N	0.0218	0.0075

Negative numbers show negative swelling, i.e. that the pelt gives up water to the solution. It will be noticed that this phenomenon occurs with the stronger solutions. As the concentration decreases, this shrinkage gradually disappears and the pelt begins to swell. The swelling attains a maximum and then decreases. The concentration for maximum swelling appears to be a specific constant for each acid. The agreement in duplicate experiments was not so good, however, in these experiments, on account of the differences in the texture of the pelt. As, moreover, the relation between the swelling of hide powder and of hide was not definite, because of the fibrous structure of the latter, further work was not attempted.—H. G. B.

Glucose in leather; Determination of — H. G. Bennett. *Collegium*, 1909, 289.

ATTENTION is called to the method of Wood and Berry (Proc. Cambridge Phil. Soc., 12, Pt. II.) for estimating glucose. Fehling's solution is reduced in the usual manner and the cuprous oxide transferred to a solution of ferric sulphate in sulphuric acid. The amount of ferrous salt thereby formed is readily determined by titration with standard permanganate. The method is said to possess considerable advantage in speed over the gravimetric method for determining the copper. The following results were obtained by independent workers in estimating glucose in a leather:—

	Method.		
	Gravimetric.	Wood and Berry.	Volumetric.
	per cent.	per cent.	per cent.
Observer (1) ..	15.7	15.3	16.7

—H. G. B.

Gelatin; Composition of — Z. H. Skraup and A. von Biehler. *Monatsh. f. Chem.*, 1909, 30, 467–479.

The authors have studied the hydrolysis of gelatin with hydrochloric acid. They find that gelatin contains no other component than was previously known to exist in it and calculate its percentage composition as follows:

glycocoll 12.4, alanine 0.6, pyrroline 10.4, leucine 9.2, aspartic acid 1.2, glutaminic acid 1.8 (the author's number), phenylalanine 1.0, oxypyroline 3.0, glutaminic acid 15.0 (E. Fischer's number, doubled), lysine 6.0, histidine 0.4, and arginine 9.3, so that the composition of dry gelatin so far as 66 per cent., is known with certainty. It is probable, however, that this number should be raised to 86 owing to loss in working, ash, &c.—J. C. C.

XV.—MANURES, &c.

Phosphatic materials containing different proportions of phosphoric acid soluble in citric acid as manures for meadows, H. Svoboda, Z. Landw. Versuchsw. Oesterr., 1908, 732. Biedermann's Zentr., 1909, 38, 540—544.

IN view of conflicting opinions as to the relative manurial value of materials containing different proportions of phosphoric acid soluble in citric acid, comparative experiments were made with: (1), and (2), samples of Thomas meal, and (3), a phosphatic chalk, the relative proportions of total phosphoric acid and of phosphoric acid soluble in citric acid in the three fertilisers being:—(1), 14.41 and 13.23; (2), 17.0 and 11.51; and (3), 23.15 and 7.00 per cent. The experiments were extended over a period of three years, in order to allow of the observation of the after-effects of the fertilisers. The results varied considerably with the nature of the weather, but on the whole the fertilisers with relatively low proportions of soluble phosphoric acid produced the greatest increase of yield in the period of the tests. Fertilisers containing a high proportion of phosphoric acid soluble in citric acid produce a considerable effect in a short time, but if the value is to be measured by the effect produced over several years, the proportion of total rather than of soluble phosphoric acid is the important factor.—A.S.

[*Sugar*] *Cane soils: Action of soluble fertilisers on* — C. F. Eckart, Report of Work of the Experiment Station of the Hawaiian Sugar Planters' Assoc., Bulletin 29, [Div. of Agric. and Chemistry,] Honolulu, Hawaii, 1909, pp. 1—88.

THE data presented were obtained from a crop of plant cane, planted in 1905, and the succeeding ratoons were cut during the present season in each of the several localities. The experiments thus practically cover a period of four years, and permit a comparison of the effects of fertilisers applied to plants and ratoons. The ordinary, so-called "agricultural method" of analysis, in which the amounts of the soil elements soluble in a solution of hydrochloric acid of definite strength (sp. gr. 1.115) are determined, was found unsuitable for affording an index of soil fertility, indicating not the availability

to plants of the important nutrients in the soil, but rather the total supplies of the essential elements. The "aspartic acid method" of Maxwell was used as giving a nearer approach to a reliable fertility-index. According to him a one per cent. solution of aspartic acid takes out of Hawaiian soils in 24 hours the same amounts of lime, potash and phosphoric acid that are removed during the production of ten crops of cane. The conclusions reached from a review of data obtained from these and other fertiliser tests are that the profit resulting from the application of fertilisers or manures will depend largely on other factors than the chemical composition of the soil. The relative effects on the growth of sugar cane of different combinations of fertiliser materials, when these materials are added to a given soil, will be determined chiefly by (a) the extent to which their several ingredients directly or indirectly lessen the deficiencies of available plant nutrients; (b) the extent to which they cause the bacterial flora to approach an optimum balance for the regular production of sufficient nitrates or assimilable nitrogen compounds, and (c) the degree and manner in which they produce physical changes in the soil. The greatest loss from the use of improper mixtures of fertilisers is apt to occur on acid soils, and in such cases considerable risk is involved from the continued application of mixtures containing ammonium sulphate, potassium sulphate, and superphosphate, when lime dressings are not previously given. The chemical and physical analysis of a soil will usually prove of value in indicating the best cultural methods to follow in maintaining or improving its fertility, and may also indicate in a general way certain of the plant food deficiencies in given cases, but the data from more extended field experiments with a large variety of soils, when reviewed in connection with the comparative analysis of the soils, using both weak and strong acids as solvents, may indicate a somewhat definite relationship between the analytical figures and the order of importance which phosphoric acid and potash should assume in cane fertilisers in given cases. Such experiments should be carried out on very long, narrow, parallel and contiguous plots or strips, with the untreated check areas lying immediately adjacent. The great importance of "resting" fields in rotation on Hawaiian plantations, and growing upon them leguminous crops, is very clearly indicated. This applies more particularly to the irrigated plantations. Nitrogen is the most important element to be considered in the fertilisation of the sugar cane in the Hawaiian Islands, and when applied in mixed fertilisers some risk of reduced efficiency is entailed if either the potash or phosphoric acid (in the form of soluble salts) be made to exceed the weight of this element. In most cases it is safer, when applying nitrogen, potash and phosphoric acid in the form of soluble salts, to arrange that the mixed fertiliser shall contain equal quantities of these elements, which are not to exceed 60 lb. per acre in the case of each element.

—L. J. DE W.

Sodium chloride (common salt) as a fertiliser for sugar beets, F. Strohmer, H. Briem, and O. Fallada, Oesterr.-Ung. Z. Zuckerind. u. Landw., 1908, 763. Biedermann's Zentr., 1909, 38, 545—546.

COMPARATIVE field experiments showed that in the case of a soil provided with a sufficiency of the ordinary plant foods, an application of common salt increases not only the yield of beetroots, but also the yield of sugar, and does not appreciably affect the quality of the beets.—A. S.

Manganese in some of its relations to the growth of pineapples, W. P. Kelley, J. Ind. and Eng. Chem., 1909, 1, 533—538.

ON some of the upland plains of the Hawaiian Islands on which pineapples are cultivated, there are black areas on which the plants will not grow well, very little fruit being produced and this of inferior size and quality, whilst the foliage acquires a yellowish-white colour. The only important difference in the chemical compositions of the black soil and the surrounding red soil is that the former contains much more manganese than the latter, and it was found that there is a close correlation between the degree of yellowing of the pineapples and the per

centage of manganese in the soil. The yellow plants are more active oxidising agents than green plants from the red soil; they have badly developed roots and contain but little chlorophyll. It is probable that the black colour of the soil is due, in part, to the presence of higher oxides of manganese.—A. S.

Sugar beets; A new proof of the favourable action of common salt in the cultivation of —. H. Briem. Deutsche Landw. Presse, 1909, 223. Biedermann's Zentr., 1909, 38, 546—548.

SOME results obtained by the application of common salt in the culture of sugar beets are shown in the following table:—

Manure per hectare (10,000 sq.m.).

		Leaves.	Beets.	Sugar.	Sugar.
		kilos.	kilos.	per cent.	kilos.
I. Unmanured		127.8	486.9	20.3	98.8
II. 300 kilos. of superphosphate	+306 kilos. of sodium nitrate	156.2	636.0	20.5	100.9
III. do.	+230 " " ammonium sulphate	162.7	551.7	19.9	109.8
IV. do.	+210 " " common salt	143.3	535.0	20.2	108.7
V. do.	+340 " " potassium nitrate	172.4	579.0	20.1	114.6
VI. do.	+150 " " ammonium sulphate and 105 kilos. of common salt	148.9	516.1	20.0	163.2

In view of these results, Strohmmer suggests that manuring with a mixture of denatured salt and ammonium sulphate might prove a satisfactory solution of the problem of replacing sodium nitrate in the cultivation of the sugar beet.—A. S.

XVI.—SUGAR, STARCH, GUM, &c.

Diffusion process; The Hyros-Rak — in the campaign, 1908—9. K. Andrlík, V. Staněk and J. Urban. Z. Zuckerind. Böhm., 1909, 33, 667—675.

THE authors have made comparative investigations of the working of the Hyros-Rak diffusion process (two batteries, of 6 and 8 diffusers respectively), and that of the ordinary process. Their results indicate that the former process can be worked continuously on the large scale and that the average loss of sugar is not greater than in the ordinary diffusion process. The exhausted slices obtained by the Hyros-Rak process were found to contain about 18 per cent. of dry substance, whereas those obtained by the ordinary process contained less than 7 per cent. The diffusion juices obtained by the Hyros-Rak process possessed practically the same average density and purity as those of the ordinary diffusion juice, and presented no difficulty in the subsequent processes of manufacture. The power required to work the Hyros-Rak process is moderate, and, in course of time, further improvement in this direction will certainly be effected. A battery of 6 diffusers should be more convenient and more economical than one consisting of 8 diffusers.—L. E.

Disaccharides of the type of trehalose; Synthesis of new —. E. Fischer and K. Delbrück. Ber., 1909, 42, 2776—2785.

If a dry, ethereal solution of β -acetobromoglucose is shaken with dry silver carbonate, and a small quantity of water is gradually added, part of the acetobromoglucose is converted into a tetraacetylglucose, whilst another part is converted into an octaacetyl derivative of a disaccharide. Two forms of the octaacetyl derivative are obtained; one of these is crystalline and probably an individual substance, whilst the other is amorphous and probably a mixture. Both forms are easily hydrolysed by barium hydroxide; the disaccharide obtained from the crystallised octaacetyl derivative has practically no reducing action on Fehling's solution, but is easily hydrolysed to *D*-glucose on warming with dilute acid. Hence, it resembles trehalose, but differs from this sugar in that its rotatory power is $[\alpha]_D^{23} = -39.4^\circ$, and the

authors therefore provisionally, call it isotrehalose, and assign the following formula to it:

Since the starred carbon atoms are asymmetric, three stereoisomerides are theoretically derivable from *D*-glucose. The disaccharide preparation obtained from the amorphous octaacetyl derivative appears to be a mixture; it differs from isotrehalose in that its rotatory power is only about $[\alpha]_D^{22} = -1.3^\circ$.—L. E.

Yield per are (100 sq.m.):

Stachyose; Action of ferments on —. J. Vintilescu. J. Pharm. Chim., 1909, 30, 167—173.

TANRET has shown that stachyose, $\text{C}_{21}\text{H}_{42}\text{O}_{21}$, is a tetrose, completely hydrolysed by dilute mineral acids into four monose molecules; namely, one each of *laevulose* and *glucose*, and two of *galactose*. He also found that with such ferments as yeast invertin, the ferments of *Aspergillus*, emulsin, and diastase, hydrolysis is, at first, but partial, one molecule of *laevulose* and one of the triose, *mannitriose*, being formed. Ultimately, this triose is slowly hydrolysed by emulsin and by *Aspergillus* ymase; the action of invertin was not determined. The author finds that with invertin the hydrolysis does not proceed further than the conversion of stachyose into *laevulose* and *mannitriose*. To complete the hydrolysis of the latter triose, the intervention of another ferment is necessary. Such a ymase occurs in the complex emulsin ferment of almonds. Emulsin, when allowed to act on the hydrolysis product subsequent to the action of invertin, effects the complete hydrolysis of the *mannitriose* molecule. This particular ferment of almond emulsin has not hitherto been indicated and has now been named *mannitriase*. It is also obtained by cultivating bakers' top-fermentation yeast in a solution of stachyose; and may be isolated by precipitating these culture liquids, without previous filtration, by means of alcohol. With these two ferments it is therefore possible to demonstrate the presence of stachyose in vegetable tissues by the biological method of Bourquelot. The aqueous extract is first subjected to the action of invertin, and subsequently to that of emulsin (or *mannitriase*). Observation of the optical deviation of the respective hydrolysis liquids will then furnish evidence of the presence or absence of stachyose.

—J. O. B.

Starch; Direct determination of —, according to the process of G. Baumert and H. Bode. G. Baumert. Z. Unters. Nahr. u. Genussm., 1909, 17, 167.

THE author proposes a modification of the above process for the determination of actual starch in potatoes, and it applies in the case of all starches of whatever source. Three grams of the most finely pulverised substance, are intimately triturated in a beaker-glass with 2—5 c.c. of water, and then, with stirring and cooling in a current of cold water, this triturated mixture is treated with 10 c.c. of hydrochloric acid of sp. gr. 1.19. After the swollen mass has at length become liquefied, which requires at most ten minutes, an excess of sodium hydroxide solution of 20 per cent. strength is gradually added, with continual stirring and cooling. The contents of the

beaker-glass are now poured and rinsed out with water into a $\frac{1}{2}$ -litre flask, filled up to the mark, and then filtered. Twenty-five c.c. of the filtrate after addition of about 1 gm. of fine floccular asbestos, whilst being vigorously stirred, are now precipitated with 50–60 c.c. of alcohol, and as soon as the precipitate has completely settled, it is collected in a previously ignited, small asbestos funnel and washed with alcohol to which 3 to 5 c.c. of dilute hydrochloric acid have been added (to decompose the sodium-starch compound), and then further washed with 80 per cent., afterwards with absolute alcohol, and finally with ether. After drying the funnel, it is weighed, and then the contents are ignited in a current of oxygen, the funnel after cooling being weighed again. The loss of weight represents the starch.

PATENTS.

[Sugar] *Finely divided material; Apparatus for drying —.* R. S. Kent, Brooklyn, New York. U.S. Pat. 914,052, March 2, 1909.

THE principal feature of the apparatus is a conveyor movable in such a manner as to pour or spill finely-divided moist material, particularly moist granulated sugar, over an edge of considerably greater length than the straight edge over which such material is usually delivered. It has been found in regular commercial use of such an apparatus that in the drying of granulated sugar, considerably over 25 per cent. of the time heretofore required to dry such sugar is saved. The inclined rotatory drum conveying the material to be dried has one or more series of blades (or flights) projecting from and lying close to the wall of the drum, some or all of the blades having irregular spilling edges, with scoop-like teeth, of considerably greater length, viewed flatwise of the blade, than a straight line connecting its terminal points. Two sets of blades may be arranged at different points in the length of the drum, the blades of one set being inclined with respect to those of the other. The drum is mounted so as to turn about an axis disposed at an acute angle to the horizontal. There are also means for passing a gaseous drying medium through the drum.—L. J. DE W.

Frothing of liquids [sugar solutions] during manipulation; Process for preventing the —. H. Hamelle. Fr. Pat. 399,855, May 5, 1908.

THE liquid is mixed with a non-saponifiable liquid lubricant, e.g., the hydrocarbons obtained from petroleum or coal-tar. These bodies, which must be of lower specific gravity than the liquid undergoing treatment, prevent the formation of froth without contaminating the product. In order to prevent the lubricant leaving the apparatus with the product, a partition or weir is provided near the point where the discharge pipe leaves the containing vessel, this weir being arranged so as to prevent the whole of the liquid from being withdrawn. The layer of lubricant which floats on the surface is thus retained and serves again for the next operation.—W. H. C.

Starch; Process for the production of soluble —. A. Païra and Die Administration der Minen von Buchsweiler Actiengesellschaft, Alsace, Germany. Eng. Pat. 9370, April 20, 1909.

IN this process, starch is rendered soluble by treating it, in admixture with dilute solutions of inorganic or organic acids, with air, best at 40°–50° C. The change is acceler-

ated by adding, either before or during the injection of the air, catalytic substances, such as salts of copper, iron, manganese, nickel, or cobalt. According to the duration of the process, the degree of solubility of the final product is regulated. If hydrochloric acid be the acid employed a 3 per cent. solution is recommended.—T. H. P.

XVII.—BREWING, WINES, SPIRITS, &c.

Malt analysis; Diastatic catalysis of hydrogen peroxid applied to —. H. van Laer. J. Inst. Brewing, 1909, 15, 553–569.

IN determining the catalytic activity of a malt, the author now uses 6 grms. of the finely-ground sample and 25 c.c. of a solution containing 0.85 gm. of hydrogen peroxide per 100 c.c. (see this J., 1906, 550), the volume of gas evolved in 1 minute being reduced to 0° C. and 760 mm. pressure and calculated on 6 grms. of the dry malt. These separate estimations should be made and the mean of the three taken, although in no case do the differences amount to as much as those frequently met with in determination of diastatic power. With the exception of malts very poor in catalase, the volume of oxygen liberated, although it increases with the amount of the enzyme present, does so less rapidly, so that the figures obtained for different malts are not proportional to their catalytic activities. With green malt kept at 20–35° C. during the first 24 hours of kilning, if there is a good draught the increase of catalytic activity, calculated on the dry matter, is insignificant; but if the kiln draws badly, and the tepid malt consequently retains its moisture at forcing temperatures, there is a considerable increase, sometimes as much as 30 per cent. on the initial figure, of the catalytic activity during the first 24 hours. While the temperature is rising from 35° C. to the final heat, the catalytic activity slowly decreases if the kiln draws well; but if the draught is bad and moisture consequently abundant, there is a rapid drop in catalytic activity as soon as 50° C. is reached. The catalytic activity of ground malt is affected by acids and alkalis in a manner contrary to that exhibited by the diastatic power, that is, it increases with the number of hydroxyl ions present in the solution of hydrogen peroxide, the maximum being reached when the mixture of peroxide and malt flour is nearly neutral to phenolphthalein. Thus, when the 25 c.c. of peroxide solution contained 1/10,000 gm.-mol. of sodium hydroxide, a malt having the catalytic activity 38 gave the value 72; further addition of alkali produced a diminution of the catalytic activity. A weaker base, such as ammonia, produces a less change. Acids of varying strength, such as hydrochloric, sulphuric and oxalic acids, diminish the catalytic activity by amounts dependent on the extents to which they are ionised. The retarding action of the chloroacetic acids increases with the amount of substituted chlorine. Glycocoll acts as a very weak base, asparagine as a very weak acid, and hydrolysable salts, such as aluminium chloride, as acids. Tri- and di-potassium phosphates act as bases and mono-potassium phosphate as an acid.—T. H. P.

Enzymes; Studies on —. II. *The measurement and influence of the concentration of hydrogen ions in enzyme actions.* S. P. L. Sørensen. Comptes rend. lab. de Carlsberg, 1909, 8, 1–168.

IN enzyme actions a distinction must be made between acidity and concentration of hydrogen ions; it is only the latter which plays a part in enzyme fissions. The concentration of hydrogen ions is best represented by its normality factor in powers of 10, e.g., a centinormal concentration of ions would be 10^{-2} , and in the case of any solution at 10^{-p} concentration of ions, p_H is termed the "exponent" of the hydrogen ions. In enzyme fissions this concentration of hydrogen ions plays a part similar to that of the temperature, and curves illustrating its influence may be plotted with the quantity of substance hydrolysed in a unit time as ordinates and the exponents of the hydrogen ion concentrations as abscissas. Such curves are very similar in appearance to the temperature curves. For measuring the concentration of hydrogen

ions in any solution, no method is permissible which involves in its performance a change of this concentration; ordinary alkalimetric methods cannot be used. The author has employed two methods: an electrical method which is accurate but laborious, and a colorimetric method which is less accurate but very simple. The electrical method depends on the measurement of the E.M.F. of a cell having one electrode of calomel immersed in a $N/10$ solution of potassium chloride, and the other electrode of platinum immersed in the liquid under examination. He has constructed curves showing the exponents of hydrogen ion concentrations equivalent to any observed E.M.F. without calculation. This method serves for the standardisation of comparative standards for the colorimetric method, which depends on the use of a number of suitable indicators which change colour within definite limits of hydrogen ion concentration. These colours are compared with known solutions prepared with mixtures of primary and secondary phosphates standardised by the electrical method. A series of 20 suitable indicators has been investigated by the author: they fall into 5 groups according to the limits governing their turning points, but all of them are not available in all cases: some of the ordinary indicators, e.g., Congo Red cannot be used at all in this class of work. A study of the action of invertase showed that the concentration of hydrogen ions most favourable to its inverting action on sucrose is practically independent of the origin and quantity of the invertase used and of the nature of the acidifying agent present. Under the conditions adopted, the optimum concentration corresponds to $p_H^+ = 4.4-4.6$. These experiments have shown the necessity, in all studies on the kinetics of the reaction, of taking into account the concentration of the hydrogen ions; neglect of this influence accounts for the discrepancies between the views of various investigators of the kinetics of inversion. The optimum concentration of hydrogen ions, in all the enzyme actions studied, changes with the duration of the action and the temperature, owing to the spontaneous decomposition of the enzymes. After prolonged action the optimum exponent for invertase tends towards the alkaline side. In the case of catalase, the optimum concentration of hydrogen ions at a temperature of 0°C . is about the neutral point, but after prolonged action it tends slightly towards the acid side. In digestions by pepsin at a temperature of 37°C . the optimum concentration of hydrogen ions is distinctly dependent on the time: for short durations the optimum exponent is slightly less than 2, but as the time is prolonged it moves towards the acid side.—J. F. B.

α - and β -Methyl-d-glucosides; The splitting of — by enzymes. H. Bierry. *Comptes. rend.*, 1909, 149, 314–316.

THE splitting of α -methyl-d-glucoside was attributed by Fischer at first to invertase, but later he regarded maltase as the active enzyme. The question however arose whether the splitting of this glucoside is actually performed by maltase or by some other enzyme which accompanies this latter in the yeast-preparations employed. This question was solved when enzymes were found in certain yeasts and in the blood and pancreatic extracts of animals which were capable of hydrolysing maltose but were inactive towards α -methyl-glucoside. By digesting the narrow intestine of the dog in presence of antiseptics, the author has obtained an extract capable of hydrolysing the α -methyl-glucoside at a temperature of 38°C . For this enzyme he proposes the name of α -glucosidase, since it appears to be different from maltase. The pancreatic extracts of the horse and dog do not hydrolyse the α -glucoside, but readily hydrolyse maltose. The intestinal extract of the dog has only a very slight action on the β -methyl-glucoside, and the pancreatic extracts are also without action upon it. The gastro-intestinal juice of *Helix pomatia* hydrolyses both the α - and the β -methyl-glucosides, but the β - compound is split far more readily than the α . The same juice rapidly hydrolyses maltose and amygdalin.—J. F. B.

Yeast; Invertase of —. E. Salkowski. *Zeits. physiol. chem.*, 1909, 61, 124–138.

IN a previous communication the author has shown that all preparations of invertase contained variable proportions of yeast gum, yielding mannose on hydrolysis, and concluded that endeavours to prepare the ferment pure, must prove fruitless so long as the sole criterion available was the inverting power of a sample (*Zeits. physiol. chem.*, 31, 305). The present research is directed to determine whether the yeast gum is an integral part of the invertase molecule, or an accidental contamination. Fresh pressed and dried yeasts were extracted with water near the freezing point, or with chloroform water, and the filtrates investigated. In all cases it was found that, contrary to usual acceptance, notable quantities of invertase were dissolved out of the cells. The chloroform water extracts were sometimes obtained free from gum, whence it is concluded that the gum is not an integral part of the invertase molecule. Invertase is not destroyed by putrefactive bacteria.—R. L. S.

Beer yeast contaminated with lactic acid bacteria; The influence of various pasteurising temperatures on top fermentation —. F. Schönfeld and W. Rommel. *Woch. f. Brau.*, 1909, 26, 397–400.

A PURE culture of yeast "A" from the Berlin brewing school collection was grown in wort alone, with cultures of various lactic acid bacteria isolated from Berlin "Weissbier" beer, and with *B. ascendens*, an acetic acid bacterium. Young, actively growing cultures and beers containing yeast and bacteria in suspension were pasteurised at $45-45^\circ\text{C}$. The results show that the yeast alone can withstand heating for half an hour at 65°C . The yeast is slightly restricted in growth and fermentative power by the lactic bacilli but is otherwise unaffected; in some instances, contrary to the statements of Henneberg, it was able to withstand higher temperatures than the bacilli. In all cases the critical temperature has been the same for both fermenting power and vegetative growth. Budding yeast cells in all cases were able to withstand higher temperatures than those present in month old beer. In presence of *B. ascendens*, budding yeast cells were destroyed at 50°C . and old cells at 45°C .—R. L. S.

Initial heats; Calculation of — and underletting heats. G. W. Smallwood. *J. Inst. Brewing*, 1909, 15, 540–549.

IN view, firstly, of the difficulty of measuring the true initial heat of a mash and, secondly, of the inaccuracy of the usual formula employed for calculating such heat, the author gives the following expression for arriving at the striking heat to be employed to obtain a certain initial heat: $[(A+BC)y+wx]/(A+B+w) - z = 0$, where $A=0.392$, $B=0.0054$, C is the percentage of moisture present in the malt, x the striking heat, y the temperature of the grist, z the initial heat of the mash and w the amount of liquor mashed per quarter, in barrels. Taking the average proportion of moisture in a malt as 3.4 per cent., the above equation simplifies to $(0.41 y+wx)/(0.41+w) - z = 0$, an extra 1 per cent. more or less of moisture lowering or raising the initial heat a little less than 0.2 degree. For the calculation of either the amount of underletting liquor at a certain temperature, or the temperature of a certain amount, to be used to raise the heat of the mash to a definite temperature, the author gives the formula: $[(A+B)z+xw]/(A+B+w) - y = 0$, where A is the amount of liquor mashed per quarter in barrels, $B=0.41$, x is the heat of the underlet liquor, y the heat of the mash after underletting, z the initial heat of the mash, and w the amount of underlet liquor in barrels. It is important that the temperature of the grist be taken into account as heat is generated during milling operations, especially where a friction mill is used; further, the grists are, as a rule, at a lower average temperature on Monday mornings than on other days, owing to the longer time of standing. The heat due to diastatic action does not enter into the equation for calculating the initial heat of a mash, the result obtained being the mean heat of the mash at the time of actual mixing. Neither does the formula for calculating the amount or temperature of the underlet liquor to be used take into account the heat

generated by diastatic action between the times of mashing and underletting; in practice, this amount of heat will probably be found to be very nearly constant and could be added to the initial heat. —T. H. P.

Brewhouse; Possible economies in the —. O. Francke
Woeh. für Brau., 1909, 26, 317.

Sifting of the grist.—The author thinks that all the advantages offered by Kubessa's and other processes, depending on the grading of the malt grist, may be gained by simpler means, e.g., preliminary mashing, "stands" during mashing for digesting proteins, steeping with warm lime-water, etc. A simple grist-mill, with long heavy rolls, giving a grist comparatively free from large particles, is more useful than a grading machine.

The protein question.—The attitude of the brewer towards the proteins has completely changed in recent years, and instead of desiring to avoid them, he endeavours to utilise them to the utmost. Thus the short high-temperature mashing process has given way to the long low-temperature methods.

Mashing and clarifying.—Malts are now shorter grown than formerly, and it is necessary, in a manner, to complete their modification in the mash tun, so as not to lose extract. The simple mashing process of the future will consist of a slow mixing process with cold preliminary mash, $\frac{1}{2}$ to 1 hour "stand" at 50° C. for the sake of the protein, a saccharification "stand" at about 70° C., decoction of the whole mash, finishing off at 75° C. by mixing in the cold infusion for completing saccharification, and clarifying through a mash filter at 75° C. The Schmitz method of clarification is destined to do good service in the future.

Omission of the boiling of the wort.—Many of the objects with which the boiling of the wort is effected are probably superfluous under modern conditions. For instance, it is not now necessary for sterilisation and caramelisation. As regards the coagulation of proteins, extraction of hops and clarification, these may be effected by the decoction of the entire mash if the finely ground hops be added to the mash tun. In this way the consumption of hops may be reduced by 25 per cent., because there is less loss of volatile matters owing to the shorter time of boiling, and the hops are fully sparged with the grains. It is desirable, however, in order to avoid gluten turbidity, to chill the wort to 0° C. before pitching, and then to warm it up again to the pitching temperature. —J. F. B.

Alcoholic fermentation; Inhibitive influence of certain acids on —. M. Rosenblatt and M. Rozenband.
Comptes rend., 1909, 149, 309—312.

In studying the inhibitive action of various acids on alcoholic fermentations the authors have established that for every acid there is a certain minimum concentration below which no effect at all is produced. They have determined this limit in each case, as well as the concentration which is required to inhibit entirely all fermentative action. These two limits bear no relation to each other. Results are tabulated for a large number of mineral and organic acids, the experiments being effected with pressed top-fermentation beer yeast in sucrose solutions, and controlled by blank fermentations without acid. The most powerfully inhibitive acid was found to be dichloroacetic acid which completely stops fermentation at a concentration of N/100; then follow benzoic and salicylic acids which inhibit fermentation at N/60 strength. Sulphuric acid only completely stops fermentation at the comparatively high concentration of 9.8 grms. per litre, or N/5, but it begins to retard it at as low a concentration as N/4000. Several acids are incapable of bringing about a complete inhibition of fermentation, even in the form of saturated solutions, such acids are *p*-hydroxybenzoic, tartaric, succinic, boric and arsenious acids, but the saturated solutions of most of these are not very concentrated. Of the ordinary organic acids which may be present in fermenting liquids, acetic acid stops fermentation at N/2 and begins to have an effect at N/100; for the other acids the corresponding limits are: lactic, 2N and N/200; isobutyric, 3N and N/100; propionic 4N and N/200; *n*-butyric, 5N and N/200; citric, N/1 and N/66. It is somewhat surprising that the fermenta-

tive action of beer yeast should resist the presence of such comparatively large proportions of acids, when the extreme sensitiveness of many enzymes to the presence of mere traces of acid is considered. This resistance is probably due to the fact that the fermentation of sugar is endocellular, and the membrane of the yeast cell is probably only slightly permeable to acids, thus protecting the internal enzymes from their toxic action. —J. F. B.

Report of the Principal Chemist of the Government Laboratory upon the work of the Laboratory for the year ended 31st March, 1909. With appendices. Wyman and Sons, Ltd., Fetter Lane, E.C., and 32, Abingdon Street, Westminster, S.W., or E. Ponsonby, 116, Grafton Street, Dublin. 1909. Price 3d. [T.R.]

The total number of analyses made in the two branches of the Government laboratory during 1908-9, was 176,922, against 191,034 in the previous 12 months—a decrease of 14,112. This, however, does not include all the analyses performed, as a large number of samples are tested at the 18 stations maintained at the outposts, and if this work is included the total number of examinations is brought up to 329,649.

Arsenic in beer, &c.—Of the 559 samples of beer, wort, and materials used by brewers, 30 were found to contain arsenic in excess of the limits laid down by the Royal Commission on Arsenical Poisoning—viz., the equivalent of one-hundredth of a grain of arsenious oxide per pound in the case of solids, or, per gallon in the case of liquids. Of 114 samples of malt examined, only one exceeded the limit, the amount found, being one twenty-fifth of a grain per pound. In 278 samples of glucose, invert sugar, caramel, &c., none exceeded the limit; the greatest amount found was $\frac{1}{2}$ this grain per gallon—this being in a yeast food.

The quantities of methylated spirits made during the years ended March 31st, 1907, 1908 and 1909, were:—

	1909.	1908.	1907.
	Bulk gallons.	Bulk gallons.	Bulk gallons.
Ordinary and industrial methylated spirit for manufacturing purposes	2,542,910	2,589,500	2,445,600
Mineralised methylated spirit, mainly for domestic use .	1,628,190	1,583,000	1,590,000
Total	4,171,100	4,173,400	4,035,600

Thus whilst there has been a decrease in the industrial or manufacturing spirit of 46,590 gallons compared with 1908, there has been an increase of nearly the same quantity in the mineralised methylated spirit used mainly for domestic purposes. The net decrease is, therefore, only 2,300 gallons. The decrease in the manufacturing spirit is probably partly due to the general trade depression that has affected all manufacturing operations during the past year. The price of alcohol used in making methylated spirit has been twice increased during the year, and now stands at a higher figure than for many years. The distillers alleged that, as the prices of the materials and fuel used by them had all increased, they had no option but to increase the price of the alcohol. The prices of the methylated spirit had, of course, to be correspondingly increased. But, although the increased prices are a serious disadvantage to manufacturers using industrial alcohol, it is pointed out that the rise in prices of alcohol has been greater in Germany and other Continental countries than in the United Kingdom. As mentioned in former reports, the quantity of industrial methylated spirit issued to manufacturers does not fully represent the quantity of such spirit actually used in manufacturing operations. In many cases this spirit is only used as a temporary solvent for one or more of the substances employed in the manufacturing operations, or for crystallising and purifying purposes. In such cases the Commissioners of Inland Revenue permit the spirit so used to be recovered by distillation, and spirit thus

covered is used again in similar operations, so that the quantity of fresh industrial methylated spirit bought by manufacturer represents the waste or loss only, and not the quantity of spirit employed in his operations. The greater efficiency in the recovery plant in recent years thus tends to somewhat mask the actual increase which has occurred in the use of methylated spirit for industrial purposes. During the year ended March 31st last, 535 applications connected with the use of methylated spirit have been referred to this department, making a total of 1,904 since the introduction of industrial methylated spirit in October, 1906. From this, it is concluded that the advantages of the new industrial methylated spirit are fully appreciated by manufacturers, and that the new regulations with reference to its use appear to be generally accepted as satisfactory by manufacturers who use the spirit.

For the preparation of mineralised methylated spirit, 94 samples of mineral naphtha representing 6,201 gallons were examined, and 202 samples representing 6,178 gallons were approved, two samples representing 23 gallons being rejected as unsuitable. Eighty-seven samples of "petroleum ether," representing 2,866 gallons, were examined, and all, except one sample representing 37 gallons, were found suitable for mixing with industrial methylated spirits used in certain manufacturing operations where an additional safeguard is required. The use of pure duty-free spirit (undenatured ethyl and methyl alcohols) in the science laboratories of universities, colleges, &c., again shows an increase compared with previous years. The quantity issued to these institutions during the year ended March 31st last was 4,815 proof gallons, against 3,323 in 1908 and 4,017 in 1907. As in the case of industrial methylated spirit, there has been a decrease in the quantity of specially denatured alcohol used for manufacturing purposes. In the year ended March 31st last only 439,038 proof gallons were issued to manufacturers as compared with 473,509 proof gallons in 1908. The quantity issued is greater than in 1907, when only 31,898 proof gallons were issued. Practically the whole of the alcohol used for manufacturing purposes, except 0,940 gallons of methylic alcohol which is not made in this country, was of British manufacture.

The total quantity of duty-free spirit expressed in proof gallons used for all purposes, domestic and manufacturing, during the years ended March 31st, 1909, 1908, and 1907, was as follows:—

	1909.	1908.	1907.
	Proof gallons.	Proof gallons.	Proof gallons.
Industrial methylated spirit for domestic use . . .	2,395,306	2,339,782	2,338,000
Industrial methylated spirit for manufacturing	3,884,739	4,115,593	3,717,000
Spirit otherwise denatured—manufacturing	439,038	473,509	432,000
Used in universities, colleges, &c.	4,815	4,323	4,000
Total	6,723,898	6,933,207	6,491,000

The total quantity of foreign spirit used for manufacturing purposes during the year ended March 31st, 1909, including pure absolute alcohol and methyl alcohol (21,185 proof gallons), was equivalent to 24,706 proof gallons, or about 15,000 bulk gallons.

For the purpose of controlling the use of methylated spirit a great many samples have been examined. Two instances of methylated spirit being used illegally in making medicinal preparations were discovered, the offenders being subsequently prosecuted and fined. Six cases of unlicensed sale of methylated spirit were also dealt with. Several cases were found where methylated spirit was being used for purposes which were not in themselves illegal, but for which the requisite authorisation had not been obtained. In these instances the traders were cautioned against a repetition of the irregularity. Many traders are authorised to use industrial alcohol in making special articles. Fifty-nine samples of industrial

alcohol have been analysed in the eight months which have elapsed since the order was issued. No cause for complaint was found in respect of 52 of these samples. The remaining seven, however, were not in accordance with the requirements, and the traders were cautioned against further disregard of the restrictions imposed. Nevertheless, the result is not unsatisfactory, as the irregularities in question were hardly in any case suggestive of intentional fraud, but rather of carelessness or an imperfect sense of responsibility.

A return of the quantities of industrial methylated spirit used in manufacturing operations and for other purposes in the United Kingdom during the years ended March 31st, 1908 and 1909, is given. The manufacturing operations enumerated are:—

Nature of Manufacturing Operations or other purposes for which the Industrial Methylated Spirit was used.	Quantity used.

Wine; Action of ultra-violet rays on the acetic fermentation of —. V. Henri and J. Schnitzler. *Comptes rend.*, 1909, 149, 312–314.

THE ultra-violet rays arrest the acetic fermentation of wine. The rays employed were obtained from a mercury lamp of quartz, and the wine was exposed in a flat dish at a distance of about 15 cm. below the lamp. Volumes of liquid ranging from 50 to 200 c.c. were exposed, in layers ranging from 1 to 4 cm. in thickness. The fermentation was studied in the case of a sour, red Algerian wine, the quantity of acetic acid already present being known. After exposure to the rays for periods of 5–30 minutes, the samples were replaced in the incubator and the further production of acetic acid was determined after 3–9 days. An exposure of 30 minutes' duration under the above conditions completely arrests the acetification. A shorter exposure produces a retardation. The appearance of the wine after 30 minutes' exposure is similar to that produced by the addition of a few drops of hydrogen peroxide; after a few days a slight precipitate of a dark colour is formed and the wine is slightly decolorised and its shade changed. The presence of air is essential for this action of the ultra-violet rays, but their action is not due to the production of ozone in the air. The active rays are those at the extreme end of the spectrum, having a wave-length below 3021. —J. F. B.

Molasses; Fermentation of Hawaiian —. S. S. Peck and N. Deerr. Hawaiian Sugar Planters Assoc., Bull. No. 28, Dept. of Agriculture and Chemistry, 1–54.

THE work described in the bulletin was carried out with the object of learning to what extent, and with what profit to the Hawaiian islands, the waste molasses of the mills could contribute to the alcohol supply of the United States, since, by the passing of the Denaturing Act of June, 1906, Congress has made possible the use of alcohol in the arts and manufactures, and in the production of light and power. In 25 Hawaiian molasses, the average content of sugars from the crop of 1908 was 51.68 per cent. Of these sugars, 83 per cent. can be converted by fermentation into alcohol. An unfermentable body, which has the same reducing power on copper solutions as glucose, is present to the extent of 6.13 per cent. of the sugars, or 3.17 per cent. of the molasses. The United States revenue regulations governing molasses distilleries, are based on an estimated yield of from 80 to 95 per cent. of proof spirit from the molasses. The yields in proof spirit of Hawaiian molasses, vary from 62 to 93 per cent., the average being 77 per cent. A modification of the regulations would be necessary before a molasses-distilling enterprise could be profitably installed in the islands. Molasses contains a sufficiency of nutrients for the development and action of yeast. Mineral stimulants give no apparent increase in the yield. Molasses contains no non-sugars which have a deleterious action on the fermentation. Aeration shortens the time of fermentation, without any increase in the yield of alcohol. Attenuation is not as great in molasses of Hawaii, as in those of most countries where molasses is fermented, on account of the smaller quantities of sugars therein. Fermentation under pure culture increased the yield in alcohol 22 per cent. over that when working under the usual factory conditions with adventitious fermentation. The lees or residue from fermentation gives a fertiliser containing potash, nitrogen, and a small quantity of phosphoric acid. Molasses as a source of alcohol and fertiliser has a value of about 8.3 cents per gallon, exclusive of freight and interest. Of the yeasts from various countries where molasses is fermented, most are budding yeasts of the type *Saccharomyces cerevisiae*; that from Peru is, however, a fission yeast. Most of the yeasts worked well in sugar concentrations up to 14.6 grms. per 100 c.c., the fermented wash containing up to 7.85 per cent. of alcohol by volume. A *Monilia* was isolated from the yeast from Natal, which gives an aroma resembling that of the best Jamaica rum. This was grown in pure culture in molasses wort; there were formed 7558 parts of esters as ethyl acetate per 100,000 of alcohol; at the same time a pure culture of yeast gave only 18 per 100,000. The esters were shown to consist

chiefly of ethyl acetate and butyrate. It is suggested that this *Monilia*, or to some closely allied form, is due to peculiar fruity odour of high-class rums. —L. J. DE W.

Whisky; Final Report of the Royal Commission on —. Blue-book (Cd. 4796), 1909.

THE present report deals with certain reservations which were made in an interim report issued in June, 1906 (this J., 1906, 825); the matters thus reserved include the advisability or otherwise of attaching special significance to particular designations, such as "Scottish whisky," "Irish whisky," "grain whisky," and "malt whisky"; of placing restrictions upon the use of such designations as trade descriptions, or of requiring such designations to be used in connection with the sale of whisky. The report also states the grounds upon which the Commissioners arrived at the conclusions set out in their interim report, and deals with subjects which they have inquired into other than whisky. A short history is given of the term "whisky" and the question of processes is dealt with at some length. During the last eight years, practically no materials other than malt and unmalted grain have been used in either pot or patent stills in Scotland, and no other materials have been used to any great extent in pot or patent stills in Ireland during the last 50 years, and the Commissioners see no reason for excluding the use of maize, which is now very extensively used in the patent still process. The conclusions of the Commissioners as to the processes of distillation may be summarised as follows:—The spirit which is produced and sold to the public in the United Kingdom at the present time under the name of whisky is distilled in various kinds of apparatus which may be broadly classified as pot and patent stills. The former are used in the manufacture of whiskies with special and pronounced characteristics in the matter of flavour and taste. They vary *inter se*, those used in Ireland for the distillation of fermented wort, derived from malt and unmalted barley, rye, and oats, differing, for example, in some respects, from those used in Scotland for the distillation of fermented worts derived from various cereals, principally maize, with the addition of a proportion of malt. The patent still is adapted for the economical production from such materials of whiskies which in general have less of the pronounced characteristics above referred to. In the distilling season 1906–7 there were in England 8, in Scotland 150, and in Ireland 27 distilleries actually working. In England 3 of these distilleries were using both pot and patent stills, and 5 patent stills only. In Scotland 137 were using pot stills only, 10 were using patent stills only, and 3 were using both pot and patent stills. In Ireland 18 were using pot stills only, 2 were using patent stills only, and 7 were using both pot and patent stills. But the patent still distilleries are of so much greater productive capacity than those using the pot still, that in the year 1907, 22,000,000 proof gals. of spirits were produced from patent still distilleries in Scotland and Ireland against 14,000,000 proof gals. produced from pot stills. Thus, nearly two-thirds of the potable spirits produced at the present time in Scotland and Ireland are distilled in patent stills. The evidence shows that such spirits have been frequently described as "whisky" by distillers and traders since the patent still came into use, and that for many years a section of the public, particularly in parts of Scotland and Ireland, has recognised patent-still spirit, without admixture, under the name of "whisky," and has purchased it as whisky, no attempt being made by the distillers or vendors to conceal the method of distillation. Moreover, spirit produced in the patent still has long been employed for blending with or diluting whiskies of different character distilled in different forms of still. This has been by far its greatest use, and most of the whisky now sold in the United Kingdom contains in greater or less degree spirit which has been obtained by patent still distillation. Again, apart from the fact that pot stills differ so much that a comprehensive legal definition would be difficult to frame without either excluding certain types of still which are now commonly recognised as pot stills, or including other types which are not now looked upon

Alcoholic liquors; Prohibition of importation of — into Iceland. Board of Trade J., Aug. 19, 1909. [T.R.]

IN virtue of an Icelandic Law which has recently received the Royal Assent, the importation into Iceland of all alcoholic liquors containing more than 2½ per cent. of alcohol is to be prohibited from the 1st January, 1912. The prohibition will not, however, apply to alcoholic liquors to be used for medicinal or ecclesiastical purposes, nor to spirit for use in industrial undertakings, chemical laboratories, natural history museums, or for use in general for burning.

Spirit industry of Austria-Hungary. Brit. and Col. Drug., Aug. 21, 1909. [T.R.]

A HEAVY fruit crop, from which unusually large amounts of fruit spirit have been produced, has lowered the demand for other alcohol. The exports of spirit to the Dalmatian Provinces have fallen off considerably, and the use of industrial alcohol has exhibited no development. In consequence of this position a spirit trust is now in course of organisation. The firms already negotiating with the view of amalgamation represent an annual production of nearly 300,000 hectolitres out of a total of about 1,600,000. The Hungarian Government proposes to reduce the quantity allowed to be distilled in the kingdom from 853,000 to 808,000 hectolitres.

Beer; Process for the treatment of — with a view to its sterilisation and the precipitation of the albumin contained therein. F. Rogerson, London. Eng. Pat. 20,086, Sept. 24, 1908.

OZONE or ozonised air under pressure is admitted into the bottling cylinder and is also admitted to the bottle before filling, and is allowed to escape from this latter into another cylinder and thence into the air. Prior to this process, the beer is admitted under pressure into the upper part of a cylinder and allowed to flow down over a gauze surface, ozone or ozonised air being admitted to said cylinder under pressure and allowed to mix intimately with the beer; the ozone or ozonised air is then allowed to escape from the cylinder under pressure, the beer being finally filtered.—T. H. P.

Fermented beverages; Process of making — by preliminary compression. E. W. Kuhn. Fr. Pat. 399,648, Feb. 19, 1909.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Meat; The application of formaldehyde to —. G. S. Buchanan and S. B. Schryver. Report to the Local Gov. Board, 1909, Food Report No. 9, 1–12.

THE report deals with an investigation on the use of formaldehyde for the preservation of meats; the methods of applying the preservative, such as washes, and treatment with formaldehyde vapour in safes and in the chilling hold of ships, are described, and the results of experiments with meat thus treated are given. It was found that formaldehyde can not only be recovered from the surface of the meat, but from parts below the surface. Portions of meat were also tested after cooking. Boiling and roasting appeared to reduce or even to remove the formaldehyde, but grilling seemed merely to make the formaldehyde penetrate further into the substance of the meat. Where muscular surface was exposed to formaldehyde vapour, the contamination was relatively large (1 in 3500), and the common depth of penetration into muscular tissue was 20 mm. under a thin superficial layer of connective

tissue. The following method for detecting and determining small quantities of formaldehyde in meat, etc. is given:—The meat is heated in a boiling water-bath for 5 minutes with water to every 10 c.c. of which have been added 2 c.c. of a 1 per cent. phenylhydrazine hydrochloride solution. In most cases, where the amount of formaldehyde is 1 part in 50,000, or less, 10 c.c. of water and 2 c.c. of the reagent are used for 10 grms. of meat. After cooling, the liquid is filtered through a loose plug of cotton-wool and to 12 c.c. of the filtrate are added 1 c.c. of 5 per cent. potassium ferricyanide solution and 4 c.c. of concentrated hydrochloric acid. In the presence of formaldehyde a brilliant magenta-like colour is developed, which reaches its full intensity in a few minutes and keeps without marked deterioration for several hours. By comparison of the colour with standards made from known amounts of formaldehyde, the amount of formaldehyde in any given sample of meat can be ascertained.

—W. P. S.

Casein; Action of methyl iodide on —. Z. H. Skraup and E. Krause. Monatsh. f. Chem., 1909, 30, 447–465.

THE authors' process for the methylation of casein is as follows:—50 grms. of casein are well stirred with 100 c.c. of absolute alcohol and a solution of 13 grms. of potassium hydroxide in 25 c.c. of absolute alcohol is added gradually in small portions. The mixture is now heated under reflux condenser with 50 grms. of methyl iodide for 2 hours. The same amount of alcoholic potash and methyl iodide is then added and the whole again heated until no further alkaline reaction is observed. Excess of methyl iodide and alcohol is distilled off, and the residue treated with 500 c.c. of boiling water, whereby a portion remains undissolved. About 190 grms. of ammonium sulphate are added and the precipitate collected. It is dissolved in three times its weight of hot, 10 per cent. alcohol and reprecipitated with ammonium sulphate; this operation is repeated five times. The precipitate is then dissolved in hot, 10 per cent. alcohol, freed from sulphuric acid by means of barium chloride, evaporated, and finally dried in a vacuum. 145 grms. of the iodine compound of methylecasein are thus obtained from 350 grms. of casein. On hydrolysis with dilute sulphuric acid no tyrosine or lysine could be detected and much less histidine and arginine, but considerably more glutamic acid, phenylalanine and leucine were obtained than from casein.—J. C. C.

Calcium sacrate in milk; Detection of —. S. Rothenfusser. Z. Untersuch. Nahr. u. Genussm., 1908, 18, 135–155.

IN the method proposed the sucrose is detected by means of a solution of diphenylamine in acetic and hydrochloric acids after the milk has been treated with ammoniacal basic lead acetate solution, in order to remove casein, lactose, etc. The author shows that when a 1 per cent. of lactose is treated with an equal volume of this clarifying reagent a precipitate is produced immediately, whilst a solution of sucrose remains perfectly clear. The details of the process are as follows:—The milk or cream is mixed with an equal volume of a solution prepared by mixing 2 vols. of basic lead acetate solution (Ph. G. IV.) with 1 vol. of 10 per cent. ammonia; the mixture of milk and reagent is well shaken and at once poured on a filter. Four c.c. of the filtrate and 8 c.c. of a solution containing 20 c.c. of 5 per cent. alcoholic solution of diphenylamine, 60 c.c. of glacial acetic acid, and 120 c.c. of hydrochloric acid (1:1), are mixed in a test-tube which is then placed in a boiling water-bath for 10 minutes. A bright blue coloration is produced if as little as 0.05 per cent. of sucrose be present; with larger quantities a deep blue colour is produced. Milk free from sucrose does not give the slightest coloration. The presence of preservatives, such as formaldehyde, hydrogen peroxide, sodium carbonate, boric acid, salicylic acid, and benzoic acid, has no influence on the sensitiveness of the test, and these substances do not themselves give a coloration with the diphenylamine reagent.—W. P. S.

Carbonophosphates in milk; The existence of — and their decomposition by pasteurisation. A. Barillé. Comptes rend., 1909, 149, 356—358.

THE presence of carbonophosphates (see this J., 1903, 193) in milk is considered by the author to be proved by the fact that calcium carbonate and dicalcium phosphate are precipitated from milk when the latter is heated to a temperature of 50° C. for 24 hours. The carbon dioxide liberated from the milk at this temperature is that formed by the dissociation of the carbonophosphates, and a determination of the soluble phosphate, the carbonophosphate, and the insoluble phosphates in milk affords a means of ascertaining what changes the phosphatic constituents of milk undergo when the milk is heated. The author finds that carbonophosphates are practically eliminated from ordinary pasteurised milks. —W. P. S.

Sterilisation by means of ultra-violet rays and its application to butter-making. Dornic and Daine. Comptes rend., 1909, 149, 354—356.

WATER may be sterilised by subjecting it to the action of ultra-violet rays, and the process is a convenient one for the treatment of water used in dairies for washing butter. It is pointed out that there is little use in sterilising the cream, if the butter, after it has been churned, is washed with water containing organisms capable of producing rancidity. The authors employ a glass-lined wooden tank containing glass partitions, over which the water flows during its passage through the tank. Two quartz electric lamps (220 volts and 3.5 amperes) are fitted in holes in the cover of the tank, but are not immersed in the water. About 3000 litres of water can be treated per day in one tank, and whilst the sterilization attained is not absolute, the number of bacteria originally present in the water is reduced to a negligible figure. For instance, water containing 11,000 bacteria (*B. fluorescens liquefaciens* and *Micrococcus prodigiosus*) per c.c., showed only 45 colonies after treatment. It is impossible to sterilise butter itself by means of ultra-violet rays, since the ozone produced by the lamps imparts an unpleasant taste to the fat; the same is the case with cream, and, to a certain extent, with milk. —W. P. S.

Manganese in some of its relations to growth of pineapples. Kelley. See XV.

PATENTS.

Food; Apparatus for preserving — by means of liquid air. J. E. Place, Glenridge, N.J., Assignor to American Air Liquefying Co., New York. U.S. Pat. 927,595, July 13, 1909.

THE apparatus comprises an insulated enclosure to be cooled, surrounding a separate insulated compartment. Inside the latter is a receptacle which is kept charged with liquid air, and is exposed to the air currents of the compartment. This holder is connected with the compartment by means of a spring valve, which is arranged to open at a predetermined light pressure. An operating "gate" connects the outer enclosure with the inner compartment, and is actuated by a thermostat, which is arranged to open or close the gate, as the temperature rises or falls in the outer enclosure. —O. (B.)—SANITATION; WATER PURIFICATION.

Nitrates; Determination of — in water containing chlorides. R. Marcellé. Ann. Chim. anal., 1909, 14, 303—304.

THE disturbing influence of chlorides on the determination of nitrates by the method of Grandval and Lajoux (this J., 1909, 740) may be overcome by rendering the chlorine insoluble, before adding the reagent. A solution of silver sulphate is added to 10—25 c.c. of the water to be examined, one or two drops in excess of the quantity calculated to

precipitate all the chloride being used; the mixture is stirred and evaporated to complete dryness on the sand-bath, and, after cooling, 1.5—2 c.c. of the reagent, instead of the usual 1 c.c., are added to the residue, and this is very carefully mixed with the reagent by means of a stirring-rod. The determination is finished in the usual way, the solution being made up to a known volume with water (the evaporating dish is rinsed out finally with ammonia); most of the precipitate is dissolved by the excess of ammonia and filtration is rarely necessary. The silver sulphate solution is prepared by dissolving 10 grms. of silver nitrate in a little water and evaporating, in the presence of sulphuric acid, until most of this acid has disappeared, a little ammonium sulphate being added towards the end of the operation; after cooling, about 40 c.c. of water are cautiously added and sufficient ammonia to completely dissolve the residue, and the volume is finally made up to 80 c.c., so that every c.c. precipitates about 25 mgrms. of chlorine. Accurate results are said to be obtained with this method, even in the presence of 5 grms. of sodium chloride per litre, and it is applicable to the determination of nitrates in effluents from sewage treatment. —F. SOPH.

XIX.—PAPER, PASTEBOARD, &c.

Papers for permanent records; Durability of —. H. W. Wiley and C. H. Merriam. Paper Specifications. E. P. Veitch. U.S. Dept. of Agric. Report No. 89, Apr. 22, 1909, 1—51. [T.R.]

THE general aim of the recommendations of the committee on paper for Departmental use, is directed towards decreasing the weight and bulk of papers by improving their quality, whereby economies of space and trans-

port charges and reduction of the waste of raw materials now occasioned by the manufacture of needlessly large amounts of heavy, inferior papers are effected. It is recognised that for certain purposes, notably the reproduction of illustrations, this principle cannot be rigorously applied, but it is desirable to reduce these exceptions to the lowest possible limits. The use of coated papers should be discouraged. Where possible, supercalendering should take the place of heavy loading or coating for giving the desired printing surface, and systematic experiments are in progress to determine the most suitable relations between the fineness of illustration blocks and the quality of the paper. A recommendation is made to the effect that a small edition of every publication should be printed on thin strong paper for distribution to public libraries, etc. The report contains a summarised account of the methods of paper testing, based, with a few modifications, on the standard German methods of procedure. The chief modification as regards apparatus is the adoption of the American bursting-strain testing machine (Mullen's type), in preference to the direct tensile-strain machine employed in Europe. The apparatus for testing transparency and folding qualities are the ordinary German models. The extreme importance of the last-mentioned test in determining the durability of the paper is fully recognised. The use of good materials properly prepared is ensured in these specifications, where necessary, by reducing the absolute values found for the mechanical properties of the paper to "specific" values, by dividing them by the relative weight of the paper, thus enforcing the principle of maximum quality with minimum weight. But the metric system is discarded, and the denominator selected for this purpose is an arbitrary one, viz. lb. per ream of 500 sheets measuring 24×36 ins. Thus the "strength factor," taking the place of the metric "breaking length," is the bursting strain in lb. divided by the weight in lb. per standard ream; the "folding factor" is the number of double folds resisted by a strip, tested under metric conditions, divided by the lb. per ream; this calculation assumes that the resistance to folding, of a given paper, increases proportionally with its weight. The breaking stretch of a paper is not taken into account in these specifications. The conception of "bulk" or specific volume, as a factor in the qualities of the paper, is adopted in the form of the "thickness factor," i.e. the thickness of the paper in ten-thousandths of an inch divided by the weight in lb. per standard ream, and each specification provides for the restriction of bulk by specifying a maximum thickness factor. Restriction of the quantity of ash is aimed at in all cases, the only papers permitted to contain more than 5 per cent. of ash being printing papers for half-tone blocks. Uncoated supercalendered papers containing 10 per cent. of ash are allowed for blocks containing up to 135 lines per inch; 25 per cent. of ash is permitted for blocks with 150 lines per inch; for finer blocks coated papers are permitted, but not for text; wherever possible the coating should be on one side only; the ash of coated papers must not exceed 10 lb. per standard ream per side. Coated papers of the first grade are specified as composed of all-rag fibres and casein is excluded from the coating composition. The ash of fine ledger, bond and post papers must be cut down to a maximum of 1 per cent.—J. F. B.

Celluloid industry in Japan. Chem. and Drug., Aug. 28, 1909. [T.R.]

THE imports of celluloid into Japan during the past four years have been as follows:—

	1905.	1906.	1907.	1908.
	£	£	£	£
Total imports	49,686	81,812	32,070	66,831
From Germany . . .	44,654	63,660	26,591	53,051
From Great Britain	4,777	15,779	4,758	11,991

The general duty on celluloid is £2 11s. per 60 kilos., and on celluloid goods the duty is 40 per cent. *ad val.*; the imports of the latter in 1907 being valued at £1,580, and in 1908 at £3,260. Of the raw materials required

to manufacture celluloid, camphor and sulphuric acid are obtained in Japan and are very cheap. It is this fact, in combination with the growing demand in East Asia, which has suggested the establishment of celluloid factories to be worked with Japanese capital. The Japanese Celluloid and Artificial Silk Factory is the principal concern. It has a nominal capital of from £100,000-£200,000, one-quarter of which has been paid up. The company will commence to manufacture celluloid at Aboshi, near Himeji, and later it will take up the manufacture of artificial silk and the chemicals necessary for the production of both articles. Two years are expected to elapse before the factory gets to work. The Sakai Celluloid Co. is building a celluloid factory at the town of Sakai. This Company has a capital of £200,000, of which £112,500 is in the hands of the founders. The buildings are expected to be completed by the beginning of 1910.

PATENTS.

Paper: Apparatus for treating fibres in the manufacture of —. P. A. Sparre, Paris. Eng. Pat. 16,104, July 29, 1908.

This apparatus, in which the fibres are pressed and macerated without being unduly reduced in length or in strength, consists of a series of troughs which hold the fibre, and stampers or beaters, pivotally suspended at the end of pivoted beams which are intermittently lifted and dropped by means of a sprocket wheel. A further set of levers, connected with the sprocket wheel, imparts a swinging motion to the beaters. By these means the beaters move alternately down each side of the troughs, and move upwards when they reach the bottom of the troughs.—T. F. B.

Paper pulp: Apparatus for making barrel bodies from —. W. H. Decker, Assignor to Solvay Process Co., both of Syracuse, N.Y. U.S. Pats. 928,247, 928,248, and 928,249, July 20, 1909.

The apparatus described has the object of producing bilged barrel-bodies direct from paper-pulp in a vat. It consists essentially of a bilged forming-roll, and a transferring roll, with a concave surface, which transfers the web and builds up the body on a bilged mandrel. The transfer roll is composed of hollow, independently rotatable sections mounted on a hollow shaft, the interior of which communicates with the interior of each of the sections. The transfer roll is in immediate contact with the bilged mandrel, but it may be driven independently by a bilged driving roll. A bilged auxiliary roll may also be interposed between the forming roll and the concave transfer roll, and out of contact with the former. This auxiliary roll receives the web of pulp from the forming roll and delivers it by gravity to the transfer roll, the bilged form of the web being preserved by blasts of air.—J. F. B.

Cellulose structures: Method of manufacturing —. P. Friedrich, Berlin. Eng. Pat. 17,967, Aug. 26, 1908. Under Int. Conv., Aug. 26, 1907.

SEE GER. Pat. 205,883 of 1907; this J., 1909, 362.—T. F. B.

Cellulose derivatives: Process for producing soluble —. L. Lilienfeld. Fr. Pat. 399,460, Feb. 13, 1909.

SEE Eng. Pat. 8708 of 1908; this J., 1909, 257.—T. F. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Ergothionine: a new alkaloid from ergot. C. Tanret. J. Pharm. Chim., 1909, 30, 145–153.

A NEW base, ergothionine, $C_8H_{15}N_3O_8S_2H_2O$, crystallising from water in rhombic lamellae, m. pt. about 290° C., with subsequent decomposition, has been isolated from the alcoholic extract of ergot. Ergothionine is soluble to the extent of 1:8.6 of water at 20° C.; very soluble in hot water; sparingly dissolved by strong alcohol; 1:30 in 60 per cent. alcohol at 20° C. and 1:6 or 1:7 in the

me at boiling point; less soluble in stronger spirit; very sparingly soluble in methyl alcohol, and in acetone; soluble in ether, chloroform, and benzene. The aqueous solutions are dextro-rotatory, $[\alpha]_D^{20} = +110$. The oil is not volatile. When freshly prepared, it is odourless; but develops an unpleasant odour on keeping. It was isolated by extracting the drug with 90 per cent. alcohol, distilling off the solvent, and removing fats and resins from the distillation residue by filtration. The latter was freed from colouring substances and more or less altered ergotinine by precipitation with 20 per cent. sulphuric acid; after removing excess of this with barium hydroxide, the filtrate was treated with basic lead acetate solution. The filtrate from this was treated with sulphuric acid to remove the excess of lead, rendered alkaline, and shaken out with chloroform to remove other bases. The separated aqueous portion was acidified with acetic acid and the ergothioneine precipitated as mercuric chloride compound by means of an 8 per cent. solution of mercuric chloride added until the precipitate at first formed, then dissolved and finally re-precipitated, ceased to increase further in volume. The mercuric chloride-compound was composed with hydrogen sulphide, and the aqueous solution of ergothioneine hydrochloride evaporated under reduced pressure to a syrup. On cooling, the salt crystallised out. The yield was about 1 per mille. The free base was obtained by treating the aqueous solution of its hydrochloride with calcium carbonate. As thus obtained it was contaminated with traces of calcium chloride, which caused it to crystallise in an acicular form. It was purified by recrystallisation from boiling 60 per cent. alcohol. Ergothioneine is a very feeble base; it does not react with litmus; but its salts are generally crystalline. The acids in these behave towards indicators as if they were free. Ergothioneine salts are precipitated by potassium-mercuric iodide, by mercuric chloride, and by solution of iodine in potassium iodide; but not by picric acid, nor by tannin; nor by sodium silicotungstate, except on very strong solutions. The free base is removed from very strong aqueous solution by tannin. When fused with kali, then treated with acid, hydrogen sulphide is evolved, when the solution of the alkaloid is heated with chloroform and potassium hydroxide, a green colour is formed, changing to blue on neutralisation. The hydrochloride, $\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2\cdot\text{HCl} + 2\text{H}_2\text{O}$, forms fine orthorhombic crystals; stable when preserved from air. Although its hydrochloric acid reacts as if free, its solutions may be evaporated dryness at 100°C . without loss of acid. Since it forms definite silver compound, $(\text{AgCl})_2(\text{C}_9\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2)_2\cdot\text{Ag}_2\text{O}$, the silver nitrate, the amount of chlorine present cannot be determined directly, but must be found by the soda-salt method. The phosphate, $\text{C}_9\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2\cdot\text{H}_3\text{PO}_4$, forms hygroscopic needles. The sulphate $(\text{C}_9\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2)_2\cdot\text{H}_2\text{SO}_4 + 1\frac{1}{2}\text{H}_2\text{O}$, is soluble 1 : 7 in water at 10°C . The hydroiodide $\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2\cdot\text{HI} + 2\text{H}_2\text{O}$ forms fine orthorhombic crystals. The mercuric-chloride, $\text{HgCl}_2(\text{C}_9\text{H}_{15}\text{N}_3\text{O}_2\text{S}_2\cdot\text{HCl})$, after first dissolving, is precipitated in needles. The platinohydrochloride is amorphous. Ergothioneine forms several ditivine compounds with iodine.—J. O. B.

Terpenes and essential oils; 109th Communication. Formation of active α -pinene from nopinone. The erythritol of terpinolene. Hydrocarbons from various sources containing terpinene. A sesquiterpene present in Siberian pine-needle oil. O. Wallach. *Annalen*, 1909, 368, 1—22.

Synthesis of active α -pinene from nopinone.—Nopinonic acid (m.pt. 84° — 85°C .) was distilled slowly in a current of hydrogen. The portions distilling below 55°C . were united, freed from acid and distilled over dium. When oxidised with excess of permanganate, the fraction yielded nopinonic acid, m.pt. 126° — 127°C ., pinene-glycol, m.pt. 75° — 77°C ., and a small amount of a keto-acid. A better yield of the keto-acid was obtained by oxidising the fraction boiling at 160° — 162°C ., using permanganate. The acid, $\text{C}_{10}\text{H}_{16}\text{O}_3$, melted at 59° — 60°C ., and had $[\alpha]_D^{20} = -93.2^\circ$ in chloroform; the micarbazone melted at 205°C . These results show the substance to be identical with β -pinonic acid, which is derived from α -pinene. The author concludes that both α -pinene and β -pinene are formed in the distillation

of nopinolacetic acid. When nopinolacetic acid is distilled with acetic anhydride, an acid, $\text{C}_{10}\text{H}_{16}\text{O}_3$, is produced, which melts at 58° — 59°C . When boiled with sodium hydroxide solution, an acid, $\text{C}_{11}\text{H}_{18}\text{O}_3$, is formed, which melts at 85° — 86°C ., and is isomeric with nopinolacetic acid. β -Pinene can be easily converted into terpin hydrate by allowing it to stand with a mixture of alcohol and nitric acid of sp. gr. 1.225. When β -pinene is oxidised with alkaline permanganate at 0°C ., nopinonic acid and a glycol, m.pt. 75° — 77°C ., are produced. The glycol when further oxidised at 50°C ., does not yield any nopinonic acid.

The erythritol of terpinolene.— γ -Terpineol, m.pt. 69°C ., was converted into terpinolene by heating on the water-bath with anhydrous formic acid. The terpinolene was oxidised with permanganate, when erythritol, $\text{C}_{10}\text{H}_{18}\text{O}_4$, was produced, which melts at 149° — 150°C . after being dried at 100°C . and 145°C .

Hydrocarbons from various sources containing terpinene.—The terpinene obtained from terpinene dihydrochloride, from pinene or from sabinene hydrate, contains two modifications, (1) α -terpinene, $\Delta^{1,3}$ -dihydrocymene, and (2) a hydrocarbon which yields erythritol, m.pt. 237°C ., on oxidation. This latter substance cannot be terpinolene, and is styled γ -terpineol, and is, perhaps, $\Delta^{1,4}$ -dihydrocymene. Bihydrocarvylamine hydrochloride on dry distillation yields a hydrocarbon boiling at 174° — 178°C ., and giving on oxidation small amounts of $\alpha\alpha'$ -dihydroxy-methylisopropyladipinic acid, and erythritol, m.pt. 237°C ., indicating the presence of a little terpinene. If the phosphate is subjected to dry distillation instead of the hydrochloride, rather larger amounts of α -terpinene are formed. Carvenone was treated with phosphorus pentachloride dissolved in light petroleum. The liquid was treated with ice-water, and the oil dried and distilled. The products obtained from several experiments differed from each other in their physical properties and in their composition.

A sesquiterpene present in Siberian pine-needle oil.—A fraction boiling between 240° and 280°C . was obtained from a Siberian pine-needle oil, which contained borneol esters and a sesquiterpene. The fraction after boiling with potassium hydroxide solution was fractionated. The portion distilling between 250° and 270°C . was dissolved in glacial acetic acid and saturated with hydrogen chloride. The mixture was treated with water, and the oil which separated, solidified in a freezing mixture. After crystallising the solid from methyl alcohol, it melted at 79° — 80°C ., and had the composition, $\text{C}_{15}\text{H}_{24}\cdot 3\text{HCl}$. When treated with sodium acetate and acetic acid, the original sesquiterpene was liberated. This boiled at 260° — 268°C . with a little decomposition, had the sp. gr. 0.8725, and n_D^{20} 1.4903 at 20°C . The corresponding hydrobromide, $\text{C}_{15}\text{H}_{24}\cdot 3\text{HBr}$, melts at 84°C . The trihydrochloride is identical with that obtained by Burgess and Page from limene (this J., 1904, 455). A similar hydrocarbon has also been obtained from opoponax oil (this J., 1904, 1236).—F. SUDOX.

Cinnamic acids from various sources. E. Erlenmeyer. *Ber.*, 1909, 42, 2649—2655.

SYNTHETIC cinnamic acid can be resolved into two isomeric acids, the cinnamic acid of storax, or natural cinnamic acid, and heterocinnamic acid. These isomerides differ in their physical properties (see *Ber.*, 1909, 42, 502). The natural cinnamic acids obtained from storax, Peru balsam, Honduras balsam, *Alpinia malaccensis*, oil of cassia, and the acid obtained from natural allocinnamic acid by the action of acetic anhydride, all have similar properties, but contain small amounts of heterocinnamic acid. The methyl ester of natural cinnamic acid was distilled. The principal portion boiled below 271°C ., and yielded pure natural acid on hydrolysis. A very small portion distilled between 271° and 275°C ., and gave an acid resembling the natural acid, but with an odour like that of heterocinnamic acid. The residue [i.e., boiling above 275°C .] yielded the synthetic acid. The acid obtained from benzalacetone by the action of sodium hypochlorite consists of a mixture of natural cinnamic acid and heterocinnamic acid. When benzaldehyde, malonic acid, and glacial acetic acid are

heated, benzalmalonic acid is produced, and when heated yields allocinnamic acid and natural cinnamic acid. The acetic acid mother liquors yielded a benzalmalonic acid which gave heterocinnamic acid on heating. The ester produced by the condensation of acetoacetic ester and benzaldehyde, when hydrolysed, yields the synthetic acid similar to that produced by the Perkin synthesis. Commercial phenylpropionic acid as well as the phenylpropionic acid prepared from synthetic cinnamic acid yield natural cinnamic acid on reduction. The propionic acid prepared from heterocinnamic acid yielded in different experiments each of the three isomerides of cinnamic acid. Various samples of cinnamic acid prepared by the Perkin synthesis, under various conditions and with altered amounts of the reacting materials, were examined and found to be identical with the synthetic cinnamic acid.—F. SUDX.

Cinnamic acids; Dependence of the differences in the — upon the original substances from which they are prepared. E. Erlenmeyer. Ber., 1909, 42, 2655—2675.

BENZALDEHYDE can be separated into two fractions. Of these, the lower-boiling fraction yields natural cinnamic acid, whilst the higher-boiling fraction yields heterocinnamic acid. Natural cinnamic acid can be obtained as follows:—(1), from natural sources; (2), from synthetic cinnamic acid by crystallisation, distillation of the esters, fractional precipitation, or through phenylpropionic acid; (3), from natural benzaldehyde containing hydrocyanic acid, from commercial benzaldehyde after distillation, from the benzaldehyde obtained by the oxidation of natural cinnamic acid, and from the benzaldehyde recovered in the ordinary synthetic process; (4), from commercial benzaldehyde in the presence of copper or copper acetate. It can also be made by methods already indicated (see preceding abstract). Synthetic cinnamic acid can be prepared:—(1), from commercial benzaldehyde; (2), from benzaldehyde free from hydrocyanic acid; (3), from benzaldehyde obtained by the oxidation of natural cinnamic acid at a high temperature and without neutralising the alkali; (4), from blood albumin; (5), from heteropropionic acid; (6), from synthetic β -bromocinnamic acid; (7), from benzalacetone; (8), from a mixture of the more or less soluble benzalmalonic acids; and (9), by mixing heterocinnamic acid and the α -cinnamic acid of storax. Heterocinnamic acid can be made:—(1), from synthetic cinnamic acid by various methods of separation; (2), from heterophenylpropionic acid; (3), from heterodibromocinnamic acid; (4), by the action of cold concentrated sulphuric acid on the synthetic acid and the natural acid; (5), from the heterobenzaldehyde obtained from heterocinnamic acid itself; (6), from the heterobenzaldehyde which is obtained by distillation from synthetic and natural benzaldehyde; (7), from the more easily soluble benzalmalonic acid. As the crystals of these three cinnamic acids are too small to be measured, the corresponding dibromides were prepared, and their measurements were found to be different. Measurements of the conductivity show that the acids differ slightly in strength. The author concludes that the differences observed in the properties of these acids is due to isomerism.—F. SUDX.

Boric acid; Volatilisation of —, by ignition in a stream of carbon tetrachloride and methyl alcohol vapours. Jannasch and Harwood. See VII.

Butyric and formic esters [esters]; Alcohol for use in making —. Oil, Paint, and Drug. Rep., Aug. 16, 1909, [T.R.]

THE U.S. Internal Revenue Bureau has refused to permit the use of denatured alcohol in the manufacture of butyric and formic esters, on the ground that such esters are chiefly used as flavouring materials in beverages, and also because a certain amount of undecomposed alcohol remains in the finished product.

The original denatured alcohol law barred this class of preparation from the benefit of the statute, but the supplemental law was enacted for the specific purpose, among others, of permitting "definite chemical substances" to be

made with the use of denatured spirits. Under this supplemental statute applications were recently made for authority to use denatured spirits in the production of these esters, but the request has been refused.

PATENTS.

Iron albuminate preparation. E. Laves, Hanover, Germany. U.S. Pat. 929,452, July 27, 1909.

A product, which remains stable in aqueous solution is prepared by mixing 30 kilos. of basic ferric chlorid solution with 200 litres of water and adding 8 kilos. of albumin dissolved in 200 litres of water; to the resulting ferric albuminate are then added 6 kilos. of ferri saccharate and 300 grms. of alkali. (See also this J. 1907, 33, 637).—W. P. S.

Azo dyestuffs [medicinal] from p-aminophenylarsinic acid. Process for preparing —. Act.-Ges. f. Anilinfabr. Ger. Pat. 212,018, June 28, 1907.

THE diazo compound of p-aminophenylarsinic acid is combined with naphthols, aminonaphthols, naphthyl amines, or their sulphonic acids. The resulting dyestuff are said to be applicable to medicinal uses.—T. F. B.

Phenylarsenious oxide and arsenobenzene; Process for preparing derivatives of —. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 212,205 Feb. 5, 1908. Addition to Ger. Pat. 206,057, April 1, 1907 (this J., 1909, 328).

HOMOLOGUES and carboxylic acids of p-aminophenylarsinic acid (with the exception of the N-dialkyl derivatives, which are disclaimed, being already known) are converted into the corresponding derivatives of phenyl arsenious oxide and arsenobenzene by reduction. The products are less toxic and stronger in their action toward trypanosomes than the arsenic acid derivatives from which they are obtained. These latter are prepared by heating o- or m-toluidine or p-xylidine with arsenious acid; the products can then be substituted in the amino groups, and the methyl groups can also be oxidised to carboxylic acid groups.—T. F. B.

Salts of disulpho-acetaldehyde sulphylic acid; Process for preparing —. Chem. Fabr. von Heyden A.-G. Ger. Pat. 212,070, July 11, 1908.

ACETALDEHYDE sulphonylates can be used as external medicaments, but they develop a mercaptan-like odour. The salts of disulphoacetaldehyde sulphylic acid do not possess this disadvantage; they may be prepared by reducing sulphurous acid, free or combined, by means of suitable reducing agents, in presence of salts of acetaldehyde-disulphonic acid.—T. F. B.

Isobornyl esters from pinene hydrochloride; Processes for manufacturing —. J. H. Lütkehermölle, Brussels. Eng. Pat. 14,752, July 11, 1908. Under Int. Conv. July 12, 1907.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Toning of P.O.P. prints: Sulphide — H. E. Smith. Phot. J., 1909, 49, 330—332.

THE following simplified process is recommended for the sulphide toning of prints on "printing-out" papers:—The prints are transferred from the frame to a solution of ammonium phosphate made alkaline with ammonium carbonate, where they remain about ten minutes, when they are fixed, without washing, in a thiosulphate solution, also made alkaline by ammonium carbonate. After thoroughly washing, they are treated with the thiomolybdate solution as before (see this J., 1908, 833).—T. F. B.

PATENTS.

Photographic printing: Method of preparing solutions used in the gum bichromate process for —. See. Anon. La Photographie des Couleurs, Antwerp, J. Sury, Wyneghem, and E. Bastyns, Antwerp. Eng. Pat. 27,686, Dec. 19, 1908.

ALL the materials necessary for the preparation of paper for the "gum bichromate" process, are mixed in powder form, agglomerated if desired by a suitable binding medium, so that the solution may be prepared at once and as required. The following example is given:—Colouring matter, 20 parts; gum arabic, 20 parts; white sugar, 1 part; potassium bichromate, 4 parts. For use, 1 gm. is dissolved in 2 c.c. of water. For making colour photographs, three different coloured mixtures are prepared, and the picture prepared by superimposition.—T. F. B.

Three-colour screens for photography: Process of making —. J. Bamber. Fr. Pat. 399,320, Feb. 11, 1909. Under Int. Conv., Feb. 13, 1908.

XXII.—EXPLOSIVES, MATCHES, &c.

Explosives: Report of the Chief Inspector of — for Cape Colony, for the year ending Dec. 31st, 1908.

THE following table gives the amounts and values of explosives imported into the Colony for the years 1907 and 1908:—

	1908.	1907.	1908.	1907.
	lb.	lb.	£	£
Dynamite: blasting compound and powder	4,374,050	4,053,190	149,039	133,807
Gunpowder	41,602	51,658	4,437	4,807
Nitrocotton	237,449	196,146	16,620	13,689
Fuse	—	—	9,914	13,903
Detonators	—	—	13,595	12,312

Of the above trade the United Kingdom takes 59 per cent., Germany, 34 per cent., Norway 5·3 per cent., Belgium 1·6 per cent., the small remaining amount coming from various other countries. 1834 samples of explosives were examined, and of this total, 1599 were blasting gelatin (the chief explosive imported), of which 1478 were passed, 66 rejected, and 55 returned as doubtful. The output of the Cape Explosives Factory, at Somerset West, during the year, was as follows:—

	Tons (2000 lb.).
Dynamite	1,605
Blasting gelatin	4,592
Gelignite	2,968
Gelatin dynamite	12·5
Total	8,577·5

The above total represents an increase of 459 tons on the previous year. The consumption of dynamite is

decreasing rapidly, blasting gelatin taking its place. Some experiments were carried out to ascertain whether local conditions had any effect on the heat test of explosives. It is well known that ozone acts upon the potassium iodide starch-paper producing discoloration, similar to that obtained in testing an explosive. It was found that heat-test papers exposed in a pine wood became discoloured within 10 minutes, whilst those placed in the open country, in the same locality, remained unaltered.

—G. W. McD.

XXIII.—ANALYTICAL CHEMISTRY.**APPARATUS.****PATENT.**

Gas analysis: Apparatus for —. G. V. Cederborg. Denver, Colo. U.S. Pat. 928,027, July 13, 1909.

THE apparatus consists of a combination of two pairs of chambers, one chamber of one pair being movable. Fixed tubes connect one pair, and a flexible tube connects the opposite pair of chambers. The first chambers and tubes contain a sealing liquid and are provided with a pipe for supplying the gases to be analysed. The introduction of the latter is regulated by automatic mechanism, and means are provided for the production of a vacuum. A tank containing an absorbing liquid is interposed between the two sets of chambers, so that the gases may be directed from the first pair of chambers, through the tank into the opposite pair of chambers, the volume of unabsorbed gases being registered in the movable chamber.—O. R.

INORGANIC—QUANTITATIVE.

Calcium and magnesium: Quantitative separation of —. W. C. Blasdale. J. Amer. Chem. Soc., 1909, 31, 917—922.

As the result of experiments with the mixed carbonates of the two metals, in proportions ranging between pure calcite and pure magnesite, the author finds that the occlusion of magnesium oxalate by the calcium precipitate may be obviated by adopting the following method of procedure. When the amount of magnesium does not greatly exceed that of the calcium present, the slightly acid solution, containing 0·6 gm. of the sample and 3·5 gm. of ammonium chloride, diluted to 300 c.c., is heated to boiling, when 1 gm. of oxalic acid is added. The liquid is then neutralised, during a period of five minutes, with a 1 per cent. solution of ammonium hydroxide, and allowed to stand for an hour before filtering. In the presence of relatively large quantities of magnesium, the precipitation is best effected in two stages, in the first of which only sufficient oxalic acid is used to combine with all the calcium, the liquid being then neutralised and allowed to stand for ten minutes, after which the remainder of the oxalic acid is added, the solution made alkaline, and allowed to stand for an hour.—W. E. F. P.

Phosphoric acid: Quantitative decomposition of metallic phosphates, with volatilisation of the —. P. Jannasch and W. Jilke. J. pr. Chem., 1909, 80, 113—127.

ALL the phosphates of this group, except that of aluminium, are completely decomposed by heating in a stream of carbon tetrachloride vapour, and the volatilised phosphorus chlorides formed can be collected in water and the phosphoric acid determined. The substance (0·3 gm., with or without admixture with powdered quartz) is placed in a quartz boat in a combustion tube drawn out at the further end, in which has been previously placed a loose plug of glass wool about 15 cm. long, the object of which is to condense the volatile metallic chloride formed. The carbon tetrachloride is volatilised from a large test-tube immersed in a bath of sulphuric acid at 200° C.; this test-tube has ground into it a tap-funnel with a capillary exit tube and a T-connection below the stopcock so that a stream of carbon dioxide or other

indifferent gas can be passed through the apparatus, and the rate of introduction of carbon tetrachloride can be varied at will. The drawn-out end of the combustion tube is connected with a tube passing through the neck of a flask containing water; the neck of the flask forms an angle of 135° with the combustion tube, and the connecting tube ends above the water in the flask. The flask is again connected with a "bull-stair" of ten or twelve bulbs, also containing water. The substance is first heated to about 200° C. in a slow stream of carbon dioxide till all water is expelled from it, and from the combustion tube; then the carbon dioxide is stopped and carbon tetrachloride vaporised, the temperature being raised to dull redness. With ferric phosphate, this suffices, but with the other phosphates of the group, an hour at this temperature and an hour and a half at bright redness are needed. When decomposition is complete the carbon tetrachloride is shut off, the carbon dioxide started, and the glass wool plug is gently heated till the whole of the carbon tetrachloride which may have condensed on it, along with any associated phosphorus compound, is driven forward into the receiver. The phosphorus in the receiver is present chiefly, though not entirely, as phosphoryl trichloride.

—J. T. D.

Vanadic acid; Quantitative decomposition of vanadium compounds with volatilisation of the —, by ignition in a stream of carbon tetrachloride vapour. P. Jannasch and H. F. Harwood. *J. pr. Chem.*, 1909, 80, 127—134.

On heating alkali-metal vanadates, and vanadium-containing minerals (vanadinite, endlicheite, carnotite) in a stream of carbon tetrachloride vapour (see preceding abstract), the vanadium is completely volatilised, and can be collected in dilute nitric acid in the receiver. The solution is afterwards reduced by means of sulphurous acid, and the vanadium determined by permanganate. If mixtures of alkali vanadate and phosphate be intimately mixed with four times as much common salt, and then heated in carbon tetrachloride for four or five hours at a temperature just insufficient to soften the combustion tube, the whole of the vanadium and phosphorus are found in the receiver; and after determining the vanadium by reduction and titration with permanganate, the phosphorus can be precipitated and determined. Alkali phosphates, which alone are unaffected by carbon tetrachloride, are completely decomposed if previously mixed with four times their weight of sodium chloride.—J. T. D.

Copper sulphate [and copper salts]; Gravimetric determination of —. P. B. Dallimore. *Pharm. J.*, 1909, 83, 271.

This new method depends on the fact that hypophosphorous acid reduces copper salts to metallic copper, just as mercurial salts are reduced to metallic mercury. Three grms. of the salt are heated on the water-bath, with constant stirring, with an excess of hypophosphorous acid diluted with an equal volume of water. Previous solution of the copper sulphate in water is not needful. In a few minutes the metal is quantitatively precipitated. The clear liquid is decanted, the precipitate collected, washed first with water, then with alcohol, and finally with ether. After drying for a few moments in a current of air it is transferred to a tared porcelain crucible, ignited until constant in weight, and weighed as cupric oxide.—J. O. B.

ORGANIC—QUANTITATIVE.

Phosphorus; Indirect colorimetric determination of — with uranium acetate and potassium ferrocyanide. R. B. Gibson and C. Estes. *J. Biol. Chem.*, 1909, 6, 349—357.

Is the method proposed for the determination of phosphorus in organic substances, the phosphorus is obtained in solution by fusing the substance with alkali and nitrate in the usual way; an excess of uranium acetate solution is then added to the solution and the uncombined uranium is determined colorimetrically after filtering off the precipitated uranium phosphate. After the substance has been fused with a mixture containing 4 parts of sodium hydroxide to 1 part of potassium nitrate, the melt is dissolved in water, the solution is acidified with sulphuric acid, boiled to remove nitric oxide, and diluted to a definite volume. Or, the substance may be digested with sulphuric acid, as in the Kjeldahl process, and the colourless solution then diluted. The phosphoric acid is determined in the dilute acid solution as follows:—*Reagents required.* (1). Standard uranium acetate solution containing 35.461 grms. of uranium acetate per litre and carefully standardised by titration (with ferrocyanide as indicator) against a disodium phosphate solution equivalent to 0.005 gm. of phosphorus pentoxide per c.c.; Fifty c.c. of this uranium acetate solution are diluted to 1000 c.c. for the colorimetric determinations. (2). Sodium acetate-acetic acid solution containing 20 grms. of sodium acetate and 100 c.c. of 30 per cent. acetic acid per litre. *Process.*—An aliquot portion of the phosphoric acid solution under examination is placed in a flask, a piece of litmus paper is added, and ammonia (sp. gr. 0.90) is run in until the solution is alkaline. The solution is boiled until the litmus paper turns red and the whole is concentrated to a volume of about 15 c.c. Five c.c. of the sodium acetate solution and 50 c.c. of the dilute uranium acetate solution are added, the mixture is diluted to exactly 100 c.c. and allowed to stand over-night. A solution containing 50 c.c. of the uranium acetate solution and 5 c.c. of the sodium acetate solution in 100 c.c. is similarly made up for comparison. The precipitated uranium phosphate is then removed by filtration and 10 c.c. of the clear filtrate are placed in a 100 c.c. measure together with 1.5 c.c. of 10 per cent. potassium ferrocyanide solution. The red-brown colour is usually fully developed in the course of 2 minutes, but there may be sufficient sulphate present to delay the development of the colour for 15 minutes. Water is next added to make the volume up to 100 c.c., and the coloration is compared with that obtained on similarly treating 10 c.c. of the comparison solution. The colour is permanent for several hours. Nitric acid and nitrates, and, to a less extent, chlorides, intensify the coloration, a maximum and constant point being reached at comparatively low concentrations of the salts. Sulphates delay the development of the colour slightly and in high concentrations have an inhibiting action. If the above directions be followed, the results obtained are, however, stated to be quite trustworthy.—W. P. S.

Formaldehyde; Determination of — in commercial solutions. O. Blank and Finkenbeiner. *Pharm. Zeit.*, 1909, 54, 624.

FORMALDEHYDE is oxidised into formic acid by means of hydrogen peroxide, and the acid thus formed is titrated. Three grms. of the solution, or 1 gm. of solid formaldehyde polymer, are treated in a capacious Erlenmeyer flask with 25 to 30 c.c. of twice normal standard sodium hydroxide solution; after 3 minutes 50 c.c. of pure (neutral) 2.5 to 3 per cent. hydrogen peroxide solution are run in, through a funnel, to prevent loss by spurring. After standing for 2 or 3 minutes, the funnel is washed down, and the free sodium hydroxide remaining is titrated back with twice normal sulphuric acid with litmus indicator. With solutions containing less than 30 per cent. of formaldehyde, the oxidation-mixture should be allowed to stand for 10 minutes before titration. The results obtained are more accurate than those of the processes of the Japanese or German pharmacopœias.—J. O. B.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Ketones; Synthesis of fatty unsaturated —. F. Bodroux and F. Taboury. Comptes rend., 1909, 149, 422—423.

WHEN ketones containing the grouping, COCH_3 , are heated with calcium carbide, condensation takes place with the elimination of water and the formation of an unsaturated ketone. Propanone forms mesityl oxide, isophorone, and xylitene. Butanone gives a ketone, $\text{C}_8\text{H}_{14}\text{O}$, which is a colourless liquid, boiling at 164°C . at 760 mm., and with the sp. gr. 0.853 at 25°C . The semicarbazone melts at 114°C .— 115°C . When reduced with hydrogen at 180°C . in the presence of nickel, the ketone is converted into a saturated ketone, which boils at 153°C .— 155°C . at 760 mm., and has the sp. gr. 0.820 at 24°C . The semicarbazone melts at 102°C . The unsaturated ketone is probably methyl-3-heptene-3-one-5. Methyl-2-pentanone-4 yields trimethyl-2,4,8-nonene-4-one-6, which is a colourless liquid with a pleasant odour, boiling at 217°C .— 219°C . at 760 mm., with the sp. gr. 0.838 at 18°C ., and with n_D^{20} 1.4491 at 18°C . The oxime boils at 143°C .— 145°C . at 17 mm. The ketone is slowly reduced by hydrogen at 280°C . in the presence of nickel, and trimethyl-2,4,8-nonanone-6 is produced. This substance boils at 210°C .— 212°C . at 760 mm., has the sp. gr. 0.820 at 18°C ., and n_D^{20} 1.4262. The oxime boils at 138°C .— 140°C . at 15 mm. Mesityl oxide yields a ketone, $\text{C}_{12}\text{H}_{18}\text{O}$. This is a yellow liquid with an unpleasant smell. It boils at 238°C .— 242°C . at 741 mm., and has the sp. gr. 0.937 at 17°C . It forms two semicarbazones, one gummy, the other melting at 165°C .— 166°C .—F. SHUX

Carbonic acid; Decomposition of — by ultraviolet rays. H. Herchfinkel. Compt. rend., 1909, 149, 395—396.

ULTRAVIOLET light decomposes dry carbon dioxide at the ordinary temperature into carbon monoxide and oxygen. In confirmation of Ramsay and Cameron's results the author also finds that carbon monoxide is produced by the action of radium emanation on carbon dioxide.—J. C. C.

Properties of radium. Extract from Address of Prof. J. J. Thomson. Brit. Assoc., Winnipeg, 1909.

BEFORE the discovery of radium it was supposed that the supplies of heat furnished by chemical changes going on in the earth were quite insignificant, and that there was nothing to replace the heat which flows from the hot interior of the earth to the colder crust. Now when the earth first solidified it only possessed a certain amount of capital in the form of heat, and if it is continually spending this capital and not gaining any fresh heat it is evident that the process cannot have been going on for more than a certain number of years, otherwise the earth would be colder than it is. Lord Kelvin in this way estimated the age of the earth to be less than 100 million years. Though the quantity of radium in the earth is an exceedingly small fraction of the mass of the earth, only amounting, according to the determinations of Strutt and Joly, to about five grms. in a cube whose side is 100 miles; yet the

amount of heat given out by this small quantity of radium is so great that it is more than enough to replace the heat which flows from the inside to the outside of the earth. This, as Rutherford has pointed out, entirely vitiates the previous method of determining the age of the earth. Strutt has shown that if radium behaves in the interior of the earth as it does at the surface, rocks similar to those in the earth's crust cannot extend to a depth of more than forty-five miles below the surface.

Though the discovery of radio-activity has taken away one method of calculating the age of the earth it has supplied another. The gas helium is given out by radio-active bodies, and since, except in beryls, it is not found in minerals which do not contain radio-active elements, it is probable that all the helium in these minerals has come from these elements. In the case of a mineral containing uranium, the parent of radium in radio-active equilibrium with radium and its products, helium will be produced at a definite rate. Helium, however, unlike the radio-active elements, is permanent and accumulates in the mineral; hence if we measure the amount of helium in a sample of rock and the amount produced by the sample in one year we can find the length of time the helium has been accumulating, and hence the age of the rock. This method, which is due to Strutt, may lead to determinations not merely of the average age of the crust of the earth, but of the ages of particular rocks and the date at which the various strata were deposited; he has, for example, shown in this way that a specimen of the mineral thoriumite must be more than 240 million years old.

The physiological and medical properties of the rays emitted by radium is a field of research in which enough has already been done to justify the hope that it may lead to considerable alleviation of human suffering. It seems quite definitely established that for some diseases, notably rodent ulcer, treatment with these rays has produced remarkable cures; it is imperative, lest we should be passing over a means of saving life and health, that the subject should be investigated in a much more systematic and extensive manner than there has yet been either time or material for. Radium is, however, so costly that few hospitals could afford to undertake pioneering work of this kind; fortunately, however, through the generosity of Sir Ernest Cassel and Lord Iveagh, a Radium Institute, under the patronage of his Majesty the King, has been founded in London for the study of the medical properties of radium, and for the treatment of patients suffering from diseases for which radium is beneficial.

Trade Report.

Foreign Patents in England.

THE Patents and Designs Act, 1907, came into force on Aug. 28 of last year so far as regards Section 27, which deals with the revocation of patents worked outside the United Kingdom. The Act gives power to any person to apply to the Comptroller-General for the revocation of a patent, after it has been in existence four years, on the ground that the patented article or process is manufactured or carried on exclusively or mainly outside the United Kingdom. During the year which has elapsed since Section 27 came into force, 69 applications for revocation of foreign patents have been made to the Comptroller-General. In 10 cases only were patents revoked by that official. In four of these cases the patentees appealed to the High Court, and in two cases relating to improvements in electric arc lamps, the decision of the Comptroller-General was reversed, evidence having been adduced which was not placed before the Comptroller-General, the effect of which was to show that the patented process was being adequately carried on in this country. The two other appeals to the High Court were unsuccessful,

so that the number of patents finally revoked was eight. Those revoked related to the following articles or processes:—Artificial stone slabs and tiles (two patents), sewing machines, umbrellas, adhesive stays or fastening straps used in box making, the lubrication of gig-mills, a steam motor-car, and locks. In another case, that of a patent connected with the manufacture of china clay, the Comptroller-General made a conditional order of revocation. The Act gives him power to revoke a patent either (a) forthwith, or (b) after such reasonable interval as may be specified in his order, unless in the meantime it is shown to his satisfaction that the patented article or process is manufactured or carried on within the United Kingdom to an adequate extent. In the case in question the patent was ordered to be revoked at the end of the present year unless in the meantime the requisite proof of "adequate" working is given. Of the other applications, four were dismissed by the Comptroller-General, in addition to the two cases in which Mr. Justice Parker reversed the decisions of that official. Twenty-eight applications were withdrawn after they had been lodged, in many cases, it is understood, because evidence was forthcoming of "adequate" working. There remain 26 cases which are still officially pending, although in one or two instances the applications have lapsed through effluxion of time.

In the first seven months of this year there were 17,869 patents applied for—an increase of 1,566 as compared with the corresponding period of 1908, though

only an increase of 319 upon the larger figures for the first seven months of 1907. Sixteen fewer patents were taken out in 1909 by American subjects than in 1908 and 331 fewer than in 1907. The decrease in German patents has been consistent—2,000 in 1907, 1,822 in 1908, and 1,735 in 1909, and the same may be said of the Austrian patents—253, 234, and 192 respectively. French patents, which were 620 in 1907 and 670 in 1908, decreased to 560 in 1909.

French patents for processes. Chem. and Drug., Aug. 21, 1909.

The Conseil d'Etat has just given a decision regarding the question of the possibility or legality of taking out French patents for processes employed in manufacturing pharmaceutical preparations. It has long been laid down that the medicament itself—that is, the remedy for human suffering—cannot be patented. This particular case dealt with an application for the patenting of a process of manufacture of a fatty substance extracted from bacterial bodies which is suitable for therapeutic use. This process, it was claimed, would produce various remedies according to the nature of the bacteria treated. The Government Commissary objected to any distinction being made between the remedy and the method of its manufacture. To patent the process was tantamount to patenting the remedy itself. The Conseil d'Etat adopted this view, and dismissed the appeal for refusal of patent.

356	Perfumery and cosmetics (e.g., hair dye, face washes and other toilet preparations) containing ether or alcohol; head, mouth or tooth washes containing ether or alcohol; perfumed or fragrant extracts (essences, tinctures) and waters containing ether or alcohol; toilet vinegar	300	400
	NOTE.—The Bundesrat is empowered to reduce the rate of 400 marks prescribed in No. 356 to 350 marks.		

Books Received.

TRINIDAD LAKE ASPHALT. PREVITÉ AND CO., 2, Crosby Square, London, E.C. 1909.

AMPHLET containing 15 pages of subject matter, and two illustrations. The matters treated of are as follows :—
I. The concession and its statistics. II. The pitch lake. III. Crude and purified Trinidad lake-asphalt, with analyses. IV. The crude and purified article compared. V. The bitumen in the Lake-asphalt. VI. The mineral matter in the asphalt. VII. The insoluble non-bituminous organic matter. VIII. The specific gravity, and melting point. IX. The refined Trinidad lake-bitumen. X. Its manufacture. XI. Fluxes to be used. XII. Analyses of two standard Lake bitumens.

Die HÄRTE DER FESTEN KÖRPER UND IHRE PHYSIKALISCH-CHEMISCHE BEDEUTUNG. Von Dr. VIKTOR PÖSCHL. Theodor Steinkopff's Verlag. Dresden. 1909. Price M. 2.50.

70 volume, containing 84 pages of subject matter, with our illustrations and one table; also an alphabetical dex of names of authors. The subject matter is arranged and classified as follows :—I. Older methods for the determination of hardness. II. Hardness, as determined by Hobeln, and Auerbach. III. Determination by

and chemical composition. XII. Hardness, chemical composition, crystalline form, and density.

ANNUAL STATEMENT OF THE TRADE OF THE UNITED KINGDOM WITH FOREIGN COUNTRIES AND BRITISH POSSESSIONS, 1908. Volume II. [Cd. 4,784]. Wyman and Sons, Fetter Lane, E.C. Price 3s. 5d.

This volume contains abstract and detailed tables of imports from, and exports to, each country; abstract and detailed tables of imports and exports at each port; tables showing the amount of Customs revenue received at each port or place; details of the transshipments under bond of certain articles; an account of the quantities of articles liable to Customs duties remaining in bond, and details of the transshipments of free goods on through bills of lading (see also this J., 1909, 820).

STATISTICAL ABSTRACT FOR THE UNITED KINGDOM IN EACH OF THE LAST FIFTEEN YEARS FROM 1894 TO 1908. [Cd. 4,805.] Wyman and Sons, Fetter Lane, E.C. Price 1s. 8d.

This publication embodies in a concise form statistical data available from official sources in regard to the finances, trade, shipping, agriculture, fisheries, railways, tramways, banking operations, &c., of the United Kingdom during the past fifteen years.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

19,118. Turquand and Turquand. Apparatus for detecting dangerous gases. Aug. 20.

19,169. Simon. Automatic recording apparatus for measuring gaseous fluids. [Ger. Appl., Nov. 2, 1908.]* Aug. 20.

19,456. Schulz and Philipp. Vessels for containing volatile and other liquids. Aug. 24.

19,626. Talansier. Apparatus for emulsifying, pulverising, and homogenising liquid. Aug. 26.

19,694. Maschinenbauges. Martini und Hüneke. Production of non-oxidising protective gas for use with inflammable liquids. [Ger. Appl., Nov. 27, 1908.]* Aug. 27.

19,709 and 19,710. Zerkowitz. Apparatus for separating liquids. [U.S. Appls., Aug. 28 and Nov. 30, 1908.]* Aug. 27.

19,767. Küppers. Apparatus for measuring gases.* Aug. 28.

19,773. Lennox. Apparatus for washing smoke, condensing steam, or evaporating water from a liquid. Aug. 28.

COMPLETE SPECIFICATIONS ACCEPTED.

17,385 (1908). Swan. Purification of steam or other gaseous media. Aug. 25.

17,564 (1908). Kerr and Graham. Drying cylinders. Sept. 1.

28,520 (1908). Sauerbrey. Cast iron evaporator having field tubes. Sept. 1.

3738 (1909). Thompson (Maschinenfabr. Augsburg-Nürnberg). Tanks for liquids. Sept. 1.

12,739 (1909). Calico Printers' Assoc., Browning, and Barlow. Apparatus for separating solid impurities from viscous or gummy solutions. Sept. 1.

12,870 (1909). White. Filters. Aug. 25.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

18,808. Weber. Manufacture of metallic filaments for incandescence lighting.* Aug. 16.

18,838. Jones. Treatment of gases from coke ovens or gas retorts. Aug. 16.

18,920. Jones. Treatment of gases from coke oven or gas retorts. Aug. 17.

18,965. British Thomson-Houston Co. (General Electric Co.). Electrodes for arc lamps, &c. Aug. 17.

19,040. British Thomson-Houston Co. (General Electric Co.). Electrodes for arc lighting. Aug. 18.

19,196. Johnston and Clark. Gas manufacture. Aug. 20.

19,300. Streubel and Wigankow. Manufacture of mantles for incandescence gas lamps.* Aug. 21.

19,357. Krause. Gas producing furnaces or ovens. Aug. 23.

19,395. Zohrab and Massey. Treatment of peat. Aug. 23.

19,419. Bröcker. Gas-producing furnaces or ovens. Aug. 24.

19,445. Coppée. Coke ovens.* Aug. 24.

19,513. Wright. Gas producers of regenerative furnaces. Aug. 25.

19,639. Cambridge. Apparatus for producing gas. Aug. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

16,333 (1908). Bechevot. Gas generators. Sept. 1.
17,978 (1908). Crossley and Rigby. Recovery of by-products in gas producer plants primarily designed for recovering ammonia. Sept. 1.

28,554 (1908). Schäffler. Manufacture of flat incandescent filaments for metallic filament lamps. Aug. 25.

4973 (1909). McKay and Cheney. Water-gas generators. Aug. 25.

5768 (1909). Schmiedt. Gas-purifying apparatus. Sept. 1.

8920 (1909). Fabry. Coke ovens. Sept. 1.

12,010 (1909). Ekenberg. Briquetting carbonised peat and the like. Sept. 1.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

19,081. Davies and Windsor-Richards. Treatment of liquid hydrocarbons. Aug. 19.

19,087. Newton (Bayer und Co.). Manufacture of ketone alcohols. Aug. 19.

19,088. Newton (Bayer und Co.). Manufacture of methylene ketones. Aug. 19.

19,157. Denner-Meier. Process for working petroleum. Aug. 20.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

18,822. Ransford (Cassella und Co.). Manufacture of sulphide dyestuffs derived from carbazol. Aug. 16.

19,086. Newton (Bayer und Co.). Manufacture of azo dyestuffs. [Addition to No. 1397 of 1909.] Aug. 19.

COMPLETE SPECIFICATIONS ACCEPTED.

21,585 (1908). Newton (Bayer und Co.). Manufacture of basic dyestuffs. Sept. 1.

25,816 (1908). Newton (Bayer und Co.). Manufacture of azo dyestuffs. Sept. 1.

26,478 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of azo colouring matters. Aug. 2.

17,546 (1909). Johnson (Badische Anilin und Soda Fabrik). See under XIII A.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

18,828. Inray (Meister, Lucius, und Brünig). Production of coloured woollen effects in unions. Aug. 16.

19,135. Amley. Treating textile piece goods, warps, &c., with liquids. Aug. 20.

- 19,213. Tate. Waterproofing fibrous materials.* Aug. 20.
 19,218. Bontemps. Machine for printing webs of textile fabric. Aug. 20.
 19,349. Aderholdt. Drying and finishing wet dyed yarns and fabrics.* Aug. 23.
 19,737. Young. Bleaching textile fabrics. Aug. 28.
 19,776. Margotin. Bleaching fabrics, threads, and other material. [Fr. Appl., Sept. 18, 1908.]* Aug. 28.

COMPLETE SPECIFICATIONS ACCEPTED.

- 17,083 (1908). Rhodes. Apparatus for treating with liquids wool, yarn, and other fibrous material. Aug. 25.
 17,713 (1908) and 2437 (1909). Calico Printers' Assoc., and Davis. Calico printing. Aug. 25.
 17,957 (1908). Johnson (Robeson). *See under XIV.*
 2313 (1909). Heimann. Treatment of fabrics. Sept. 1.
 6486 (1909). Dean. Vats for dyeing, &c. Aug. 25.
 6876 (1909). Meister, Lucius, and Brünig. Producing colour effects on fabrics. Aug. 25.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 18,816. Boulton (Kritzer). Lime-hydrating apparatus.* Aug. 16.
 18,825. Sulphates, Ltd., Thwaites, and Ralph. Treating liquors containing metallic compounds to obtain iron, zinc, and cobalt compounds. Aug. 16.
 18,923. Boulton (Ladd). *See under VIII.*
 18,945. Beindl. Production of hydrocyanides and cyanides. Aug. 17.
 19,689. Johnson (Badische Anilin und Soda Fabrik). Continuous production of nitric acid. Aug. 27.
 19,755. Chem. Werke vorm. Dr. H. Byk, and Schmidt. Manufacture of borates containing active oxygen.* Aug. 28.

COMPLETE SPECIFICATIONS ACCEPTED.

- 17,220 (1908). Hertkorn. Products containing iodine. Aug. 25.
 17,520 (1908). Kühne. Removal of sulphur dioxide from gases and its recovery as sulphuric acid. Aug. 25.
 17,608 (1908). Mond. Producing iron carbonyl. Aug. 25.
 17,978 (1908). Crossley and Rigby. *See under II.*
 19,528 (1908). Ashworth. Production of reducing agents. Aug. 25.
 794 (1909). Bailey and Stevenson. Production of borax from native boron compounds. Aug. 25.
 4494 (1909). Beskow and Ekedahl. Removing superphosphates from decomposition chambers. Sept. 1.
 9145 (1909). Cie. Indus. des Alcools de l'Ardèche. Recovery of sulphurous acid from solutions. Aug. 25.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

- 18,923. Boulton (Ladd). Treatment of clay, bauxite, kaolin, &c.* Aug. 17.
 19,080. Doulton and Noke. Decoration of pottery. Aug. 19.
 19,282. Clark and Johnson. Machine for dipping and glazing tiles, pottery ware, bricks, &c. Aug. 21.

COMPLETE SPECIFICATION ACCEPTED.

- 17,432 and 17,433 (1908). Ling, Rendle, and Colbrook. Reproduction of images on glass, ceramic, metallic, or other surfaces. Aug. 25.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 18,887. Forrester (Blanc Stainless Cement Co.). Manufacture of Portland cement.* Aug. 17.
 18,997. Nash. Cement kiln.* Aug. 18.

- 19,282. Clark and Johnson. *See under VIII.*
 19,459. Lake (Pine Street Patents Co.). Manufacture of cement clinker.* Aug. 24.
 19,460. Coward. Composition for making waterproof paving slabs, building blocks, &c. Aug. 24.

COMPLETE SPECIFICATION ACCEPTED.

- 25,637 (1908). Winkler. Building material capable of replacing wood. Sept. 1.

X.—METALS AND METALLURGY.

APPLICATIONS.

- 18,817. Hommel and Durant. Treatment of complex zinc ores. Aug. 16.
 18,826. Gröndal. Concentrating oolitic ironstone and similar iron ores.* Aug. 16.
 18,962. Wolff. Treating metals for desulphurising and deoxidising purposes.* Aug. 17.
 18,996. Gutensohn. Recovery of zinc, lead, and silver from their sulphide ores. Aug. 18.
 19,091. Woolford. Collection of metallic fumes. Aug. 19.
 19,092. Woolford. *See under XIII.A.*
 19,308 and 19,309. Boulton (Ashcroft). *See under XI.*
 19,386. MacIvor, Hommel, and Metals Extraction Corporation. Manufacture of zinc oxide for smelting. Aug. 23.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 55, Rue des Francs Bourgeois, Paris (3^e).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Evaporating boilers for use in the crystallisation of liquids. O. Faller, Munich, Germany. Eng. Pat. 16,817, Aug. 10, 1908.

THE boiler is provided with a wide central return flow tube, on each side of which a group of inclined heating tubes, surrounded by a steam jacket, is arranged. The heating tubes are made narrow to promote rapid circulation and thus prevent incrustation, and are inclined in order that any crystals formed in the liquid during its passage up the tubes may be projected into the central return tube. The latter is made of greater cross-section than the sum of the cross-sections of the heating tubes, and is prolonged downwards so that the returning liquid has a long period of comparative rest to enable the crystals to attain such dimensions that they are not easily drawn up again with the circulating liquid into the heating tubes.

—W. H. C.

Raising and forcing water and other liquids and semi-liquids. B. C. Joy, London. Eng. Pats. 17,500, Aug. 20, 1908, and 3407, Feb. 11, 1909.

A CLOSED vessel provided with inlet and outlet valves and mains for the liquid to be raised is connected by non-return valves to a supply of explosive gas and to a supply of water. When the pressure within the vessel is lower than or equal to that of the atmosphere, both the liquid to be raised and the explosive gas enter the vessel. As soon as the pressure rises above that of the atmosphere, the liquid and gas inlet valves close, the resistance of the spring controlling the ignition device is overcome, and the explosive mixture is fired. The pressure resulting from the explosion drives the liquid up the delivery main until the pressure has fallen again to that of the atmosphere, when the non-return valve on this main closes. Water is now injected into the vessel and assists in cooling the residual gases, with the result that a partial vacuum is formed within the vessel and it begins to fill again.

—W. H. C.

Dipping tanks. Wilkinson, Heywood and Clark, Ltd., London, and C. Gordon, Blackheath. Eng. Pat. 8164, April 5, 1909.

IN order to facilitate the removal of the agitating gear from a dipping tank in which objects are dipped into paint or varnish, etc., the horizontal agitator which works in the bottom of the tank is driven by an easily removable vertical shaft placed at one end of the tank. This shaft is provided at its lower and upper ends with bevel wheels, which engage respectively with a bevel wheel on the end of the agitator shaft, and with the driving mechanism.—W. H. C.

Melting apparatus. W. M. Carr, New York, Assignor to C. H. Speer, Chester, Pa. U.S. Pat. 929,831, Aug. 3, 1909.

A CRUCIBLE or container is supported within a refractory casing or jacket, so as to leave a narrow flame passage around the crucible. Suitable fuel is introduced through an opening near the bottom of the casing and is supplied with air for its combustion through the hollow trunnions on which the casing is supported. The air passes from the trunnions through a tortuous passage

formed in the walls of the casing adjoining the flame passage and becomes heated on its way to the combustion chamber.—W. H. C.

Refrigerating systems; Separating oil from ammonia in — C. D. Bauer, Springfield, Ohio. U.S. Pat. 930,128, Aug. 3, 1909.

THE oil and ammonia flow from the refrigerating apparatus through a trap to a tank heated by a steam coil and provided below with an outlet for the oil. From the top of this vessel the ammonia vapour passes to a second tank connected to the suction side of the pump of the refrigerating apparatus and cooled internally by a water coil and externally by water spray.—W. H. C.

Carbonator. L. M. Keeler, Scarsdale, and J. Rampp, New York. U.S. Pat. 930,189, Aug. 3, 1908.

THE apparatus consists of a closed chamber having at its upper part a vertical cylinder. The combined gas and liquid inlet pipe enters the top of this cylinder and discharges into a central conduit around which are arranged a number of chambers with small discharge openings in their lower surfaces, the lower of these chambers being provided with circumferential rims extending below the bottoms of the chambers. The liquid is discharged through the small openings and falls into the main chamber.—W. P. S.

Furnace. W. C. Willan, Charleston, S.C., Assignor to The Libbey Glass Co., Toledo, Ohio. U.S. Pat. 931,663, Aug. 17, 1909.

THE claim is for a furnace provided with a central vertical shaft extending through the floor of the furnace and driven by worm gear from below. A table is supported upon the shaft within the furnace and is rotated. The furnace is provided with suitable openings in the side wall for the introduction and withdrawal of the articles to be heated, which are placed upon and rotated with the table. The table is also provided with several vertical shafts arranged in a ring, the shafts passing through the table. Each of these shafts carries a smaller table at the upper end and at the lower end is provided with a gear wheel which engages with a toothed ring set in the floor of the furnace, so that as the larger table rotates, each of the smaller tables is independently rotated.—W. H. C.

Separating liquids of different specific gravity, especially fat and glue solution; Apparatus for — H. Meyer. Ger. Pat. 212,643, Sept. 27, 1907.

THE mixture of liquids is introduced through a pipe into a vessel in which separation takes place by gravity. As the level of the mixture rises, the lighter liquid flows over the edge of a receptacle disposed within the vessel, whilst the heavier liquid flows out at the bottom through a pipe, which is bent at right angles, and then extends upwards nearly to the height of the rim of the inner receptacle. The difference between the heights of this pipe and the rim of the inner receptacle is so adjusted in relation to the difference between the specific gravities of the two liquids, that only the lighter liquid can flow into the inner receptacle, and only the heavier one can overflow from the pipe. In using the apparatus for the separation of fat from glue solutions, the vessel is preferably mounted in the upper part of the evaporator; the fat flows into the inner receptacle, and the glue solution

overflows from the pipe into the evaporator, so that evaporation and separation of the fat are effected in one apparatus at the same time.—A. S.

Gases or vapours; Apparatus for subjecting — to the action of liquids. C. H. Fowler and E. A. Medley, Great Crosby, U.S. Pat. 928,118, July 13, 1909.

SEE Eng. Pat. 27,391 of 1908; this J., 1908, 1196. —T. F. B.

Furnace; Hearth —. F. Dahl, Bruckhausen, Germany. U.S. Pat. 931,916, Aug. 24, 1909.

SEE Eng. Pat. 21,103 of 1907; this J., 1908, 1007. —T. F. B.

II.—FUEL, GAS, AND LIGHT.

Combustible gases; Systematic separation of —. G. de Voldere, Bull. Soc. Chim. Belg., 1909, 23, 323–346.

THE author suggests a general method for the quantitative analysis of a gaseous mixture which may contain nitrogen, oxygen, hydrogen, carbon monoxide, carbon dioxide, and hydrocarbons of the series, C_nH_{2n+2} , C_nH_{2n} , C_nH_{2n-2} , C_nH_{2n-4} , and C_nH_{2n-6} . The method consists in the successive absorption of groups of gases by suitable reagents, together with determinations of the contraction and of the volume of carbon dioxide formed on complete combustion, before and after each such absorption. The first operation is the complete combustion of a part of the gas, giving a contraction, C_1 , and yielding a volume of carbon dioxide equal to D_1 ; by absorbing the excess of oxygen after the combustion, the nitrogen is directly determined. A separate portion of the original gas is next treated with alkaline pyrogallate, which absorbs a volume, C_2 , made up of a volume, x , of carbon dioxide, y , of oxygen, and z , representing a part of the hydrocarbons, C_nH_{2n-6} . A portion of the residue left after the absorption is exploded, giving a contraction, C_3 , and a volume, D_3 , of carbon dioxide. The differences, $C=C_1-C_3$ and $D=D_1-D_3$, are the values due to the combustion of a mixture consisting of volumes, x of carbon dioxide, y of oxygen, and z of hydrocarbons, C_nH_{2n-6} . The observed data are sufficient for the determination of x , y and z with the aid of the known relations, $C=y+z$; $D=x+6z$, and $C_2=x+y+z$. The analysis is continued in a similar manner with the residue from the first absorption, the absorbents used being fuming nitric acid which absorbs the remainder of the gases, C_nH_{2n-6} , and a part of the carbon monoxide, and afterwards fuming sulphuric acid or bromine water which absorbs the gases, C_nH_{2n} and C_nH_{2n-2} . The residue from the final absorption consists of carbon monoxide, hydrocarbons, C_nH_{2n+2} (including hydrogen), and nitrogen, and the final combustion gives the data for determining the three corresponding volumes; the quantity of hydrogen may be determined separately by partial combustion of a portion of this residue with palladium-asbestos. It will be seen that the method does not permit of the separate determination of hydrocarbons of the same series unless special absorbents are available. The limitations of the method are given generally by the following laws, in which hydrogen is to be included in the series, C_nH_{2n+2} , carbon dioxide in the series, C_nH_{2n-6} , and oxygen and carbon monoxide in the series C_nH_{2n-4} :—It is not possible by a single complete combustion to determine the constituents of a mixture containing: (1), more than two members of the same series; (2), more than three members belonging to different series, and in each case the formula of each gas must be known; and (3), it is not possible by a single complete combustion to determine the total volumes of gases of each series in a mixture containing gases of more than two series, and the nature of the two series must be known. The converse of (2) is not always true—for example, a mixture of methane, carbon dioxide, and carbon monoxide cannot be analysed by a

combustion only; but a mixture containing two gases of one series and one gas of another series can always be so analysed. The analytical methods commonly use are shown to be particular cases of the general method described.—A. T. L.

PATENTS.

Fuel. G. B. Selden, Rochester, N.Y. U.S. Pat. 929,500, July 27, 1909.

AN improved fuel for internal combustion engines prepared by adding to a liquid hydrocarbon, a volatile peroxide or a vehicle carrying the same, and a nitr compound such as nitrobenzene.—R. L.

Coke-ovens; Horizontal regenerative —. H. V. Seymour, Leeds. Eng. Pat. 21,249, Oct. 8, 1908.

Two superposed flues are constructed beneath the soot wall of each oven and are each separately connected to the regenerator flues which are placed side by side, longitudinally, one on either side of the centre line, below the battery of ovens. The vertical heating flues on each side of the oven are alternately connected to one or other of the sole flues. The heating gas is supplied by pipes to a flue which passes beneath the vertical flues in each side wall of the oven. In one phase of the working, the gas enters the bottom of each alternate vertical flue and then meets the preheated air from one of the sole flues connected to the regenerator which is in communication with the air. The gas burns and the products of combustion pass up one vertical flue and down the next to the other sole flue, which is connected to the other regenerator in communication with the chimney. When the dampers are reversed, the currents of gas and air flow in the reverse directions.—W. H. C.

Gas producers. B. Versen, Dortmund. Eng. Pat. 16,610, Aug. 6, 1908.

THE patent relates to producers of the type in which air mixed with gaseous products of distillation from the upper part of the producer is delivered into the centre of the combustion zone, and the invention consists mainly in forming the central blast-pipe of inverted conical form whilst the walls of the producer chamber at the level of the combustion zone are of conical form, so that the area of the fuel column increases rapidly as the fuel descends through the combustion zone, the object being to prevent the clinker hanging up. The conduit for the distillation gases passes centrally down through the fuel column to the combustion zone, and the air-supply pipe may pass down the interior of this conduit, or it may pass up from the lower part of the producer and open into the lower part of the gas conduit. The lower conical portion of the gas conduit, forming the blast-pipe is water-jacketed and the lower part of the producer forms a water-trough for the reception of the clinker.—A. T. L.

Gases; Process of obtaining by-products from —. G. Hilgenstock, Dahlhausen-on-Ruhr, Germany. U.S. Pat. 928,974, July 27, 1909.

FOR the extraction of by-products from the gases of the dry distillation of coal, the gas coming from the retorts or coke ovens during the first period of the process, and containing the greater part of the tar, is separated from the substantially tar-free portion of the gas of the later period and is freed from its tar contents by injecting tar through it. Both portions of gas are subsequently combined and led into an acid bath for the extraction of ammonia.—R. L.

Gas washer. G. Wilton, London. U.S. Pat. 929,358, July 27, 1909.

THE gas washer comprises several washing units each consisting of a series of superimposed chambers provided with a liquid seal and bubbling hood device, and with a supplemental detachable apron in the form of an inverted tray resting on the hood. The hood, which is immersed in the liquid at considerable depth, has serrated edges and the apron has suitable perforations. Each washing unit has a liquid inlet at the top and an outlet at the bottom. The gas-supply main is common to all the

units, but supplies each independently from the others, and all the units discharge into a common gas-collecting main. Thereby the gas may be so divided into several streams that each is being washed in one unit only.—R. L.

Gas-purifier. T. A. Edison, Llewellyn Park, West Orange, N.J., Assignor to Edison Portland Cement Co., Stewartsville, N.J. U.S. Pat. 930,947, Aug. 10, 1909.

Dust is removed from gases by passing them through a filtering chamber containing shelves oppositely inclined and facing each other. Granular filtering material is supported by these shelves, which are arranged so that the plane of each shelf intersects the next lower oppositely inclined shelf. Means are arranged for continuously feeding the filtering material in at the top of the filtering chamber and removing it, together with the dust retained, from the bottom of the chamber, so that the filter always maintains the same degree of porosity. (See also U.S. Pats. 930,946, 930,948, and 930,949, page 984.)—A. G. L.

Producer gas; Purification of — L. A. Chevalet. Fr. Pat. 400,333, May 30, 1908.

The gas is freed from the tar which passes through the ordinary scrubbers and mechanical washers, by a final washing with a solvent oil such as creosote or anthracene oil. This final washing may be carried out in any known type of scrubber, and the patent covers the use of any oil obtained in the distillation of tar and boiling above 50° C.—A. T. L.

Incandescent mantles; Manufacture of — by the impregnation of fine threads with hydrated peroxides. J. Visseaux. Fr. Pat. 400,178, May 22, 1908.

The fabric of the mantle is first impregnated with salts of rare earth metals in the usual way and then soaked in a bath of concentrated hydrogen peroxide for two hours in order to convert the salts into the hydrated peroxides. The mantle is afterwards washed in water, dried, and incinerated.—A. T. L.

Incandescent mantles; Manufacture of — Soc. Française de Chaleur et Lumière. Fr. Pat. 400,378, Mar. 5, 1909.

The fabric of the mantle is woven with threads of artificial silk together with threads of ramie or cotton, thus combining the advantages of both materials.—A. T. L.

Incandescent gas mantles; Manufacture of — from artificial silk. R. Böhm. Fr. Pat. 400,444, Mar. 8, 1909.

Fabric of artificial silk is impregnated with the thorium and cerium salts of organic acids, such as the citrates, acetates, or with a mixture of these salts and the salts of mineral acids such as the nitrates. The impregnated fabric may afterwards be passed through an alkaline bath or through hydrogen peroxide, or it may be treated with alkaline vapours, in order to convert the salts into insoluble compounds.—A. T. L.

Combustible mixtures for producing actinic light. C. Bethge, Berlin. Eng. Pat. 16,448, Aug. 4, 1908.

The patent is for a slow-burning mixture of a reducible oxygen compound of a readily combustible rare earth metal with an excess of magnesium amounting to from 10 to 100 times the equivalent of the oxygen in such compound, with the addition of a small percentage of a radium compound if desired. The magnesium may be replaced by aluminium, calcium, barium, or strontium. The examples of suitable mixtures are 250 parts of magnesium powder with one of the following:—150 parts cerium oxide, with or without 8 parts of vanadic acid; 100 parts of cerium oxalate; 75 parts of calcium hydroxide; 50 parts each of cerium oxide and calcium hydroxide; 25 parts of manganese oxide; or 50 parts of cerium oxide and 25 parts of manganese oxide. In burning, the oxygen compound is reduced by the magnesium, the cerium or other metal is oxidised, and the oxide again reduced so long as there is an excess of magnesium present. 2 to 3 grams of these mixtures will burn for 30 seconds. Reference

is directed to Eng. Pats. 23,292 of 1901, and 3794, 27,267 and 27,268 of 1904 (this J., 1902, 792; 1905, 44, 210). —A. T. L.

Pyrophorous substances; Process for the manufacture of — for ignition and illumination. A. Lesmüller, München, Bavaria. Eng. Pat. 27,341, Dec. 16, 1908.

For the production of pyrophorous substances the rare-earth metals have been alloyed, by means of an electrolytic process, with other harder metals, e.g., iron. The patent claims the use of non-metals, e.g., silicon, titanium or boron, in place of metals, for this purpose. The substances so produced are very hard, economical in use and less subject to oxidation. The temperature of ignition is very low, so that when the pyrophorous substances are rubbed against a harder body, small particles are detached which inflame at once in the open air, and are adapted for igniting combustible gases. The addition of oxidising bodies produces substances suitable for flash-lights, etc. The alloys may be prepared:—(1), by mixing the silicon, titanium, etc., with the rare-earth metals in the decomposition chamber in which these have been separated by electrolysis; (2), by melting the metals in a magnesia crucible, under a cover of a molten salt, such as sodium chloride, to exclude air, and adding the silicon; (3), by fusing the metals either in an indifferent gas or in a vacuum before adding the silicon.—G. W. McD.

Filaments [for electric incandescence lamps]; Treating metal — C. T. Fuller, Schenectady, N.Y., Assignor to General Electric Company, New York. U.S. Pat. 929,578, July 27, 1909.

An oxide of tungsten is mixed with a carbonaceous binding material and the mixture so formed is shaped into threads. A number of these is baked in an atmosphere of hydrogen to effect complete reduction of the oxide. The filaments are subsequently fired to about 1500° C. in a reducing atmosphere until free from carbon, and the heating is continued until the tungsten is sintered to a condition of stable conductivity.—R. Carbon bisulphide in benzol; Determination of —.
J. M. Weiss. *J. Ind. and Eng. Chem.*, 1909, 1, 604—605.

THE method is based on the conversion of the carbon bisulphide into potassium xanthate, the oxidation of the latter, and precipitation of the sulphur as barium sulphate. About 2.5 grms. of the benzol are treated with 2.5 c.c. of a saturated solution of potassium hydroxide in absolute alcohol, and after five minutes the mixture is heated at 60° C. for 1 hour under a reflux condenser. After addition of water, the benzol is expelled by heating on a steam bath, the aqueous solution is made strongly alkaline with potassium hydroxide, and excess of bromine water is added. The whole is heated, and if necessary more bromine water added, until oxidation is complete. The solution is then acidified, the excess of bromine expelled, and the sulphur determined as barium sulphate in the usual manner.—A. S.

Heptane (dimethyl-2,4-pentane); A new —, and its occurrence in Caucasian petroleum. G. Choum. *J. Russ. Phys.-Chem. Ges.*, 1909, 41, 327—344. *Chem. Zentr.*, 1909, 2, 587.

DIMETHYL-2,4-PENTANE was prepared from dimethylisobutylcarbinol by converting this into dimethyl-2,4-iodo-4-pentane by the action of hydrogen iodide gas in the cold, and then heating the iodo-derivative with fuming hydriodic acid in a sealed tube for seven hours at 200°—230° C. From the hydrocarbon the nitro-, amino-, and phenylthiourea derivatives were prepared, and these were found to be identical with the corresponding derivatives prepared from the fraction of Caucasian petroleum boiling at 80°—82° C. Dimethyl-2,4-pentane is a mobile liquid with a petroleum-like odour, b.pt., 83°—84° at 764 mm.; sp. gr. 0.6971 at 0° C., 0.6805 at 20° C.; $n_{20}^D=1.3825$; it is easily soluble in nitric acid of sp. gr. 1.52. Dimethyl-2,4-nitro-4-pentane prepared by heating the hydrocarbon with dilute nitric acid in a sealed tube for 9 hours at 100°—105° C. is a nearly colourless liquid with a camphor-like odour.—A. S.

Polynaphthenic acids. K. Charitschkoff. *J. Russ. Phys.-Chem. Ges.*, 1909, 41, 345—353. *Chem. Zentr.*, 1909, 2, 708.

A FRACTION of (Caucasian) petroleum boiling at 161°—166° C. at 754 mm., and having the sp. gr. 0.7800 at 15° C., yielded, when oxidised with air (compare this *J.*, 1909, 303), syrupy dibasic polynaphthenic acids, $C_{21}H_{24}O_4$, probably formed by the condensation of three molecules of naphthenic acids. These acids were easily soluble in benzene, toluene, alcohol, and carbon bisulphide, but only slightly soluble in petroleum spirit (ligron). A synthetic heptanaphthene (dimethylpentamethylene) prepared from toluene by reduction with hydriodic acid, yielded on oxidation in a similar manner, naphthenic or polynaphthenic acids. Distillates from Grosny petroleum behaved in an analogous manner. Cymene yielded cumic acid, and menthane gave a mixture of naphthenic and polynaphthenic acids.—A. S.

Analysis of calcareous asphaltum and paving mixtures.
Prettner. See IX.

PATENTS.

Ammonium sulphate; Saturator for the manufacture of —. E. A. Brotherton and W. Wyld, Leeds. *Eng. Pat.* 14,349, July 7, 1908.

THE saturator consists of an enclosed vessel, having an inclined bottom, and the upper portion divided into compartments by one or more depending partitions, serrated or perforated, or serrated and perforated, at their lower extremities. Gas inlet and outlet pipes are provided, and means whereby the acid may be introduced into the compartment nearest the gas outlet. The

vapours, as they travel towards the outlet, have to pass through a liquid of increasing acidity in each compartment. The partitions are of suitable depth to secure the requisite seal in the liquid, and, if more than one be employed, that nearest the ammonia inlet is the lowest, each succeeding partition having its bottom edge at a higher level than the preceding one. More thorough washing is effected in this, than in the usual type of vessel, local alkalinity also is avoided, and the separated sulphate readily flows down to the discharge valve.—F. SODS.

Ammonia gas from ammonia liquors; Method of obtaining purified —. C. M. Stine, Chester, Pa., Assignor to The E. I. du Pont de Nemours Powder Co., Wilmington, Del. *U.S. Pat.* 929,726, Aug. 3, 1909.

TO obtain purified ammonia gas from ammonia liquors, a current of air is forced through the liquor, and, at the same time, the temperature is gradually raised to 100° C. or above.—F. SODS.

Melting bitumen material, pitch, marine glue, grease and the like; Boilers for —. J. Allan and J. Richmond, Glasgow. *Eng. Pat.* 11,557, Nov. 30, 1908.

THE claim is for a pitch boiler or melter of an elongated form provided with a cover and an outlet for the melted pitch, and supported on brackets within a casing. A hollow cone is formed within the boiler projecting upwards from the bottom to enable the heat to penetrate more easily the contents of the vessel. The cone is provided with an outlet above for the escape of the waste gases. The boiler is heated by burners supplied with liquid fuel under pressure from a store tank placed below.

—W. H. C.

Crude petroleum and illuminating oil; Process for transforming — into spirit (distilling below 150° C.). P. Sabatier. *Fr. Pat.* 400,141, May 21, 1908.

THE oil is vaporised and passed over finely divided metals heated to between 400° C. and a dull red heat. It is converted partly into gas and partly into low-boiling, unsaturated, oxidisable bodies of unpleasant odour. The latter are passed along with hydrogen or gases rich in hydrogen over finely divided metal, preferably nickel heated to between 150° and 300° C., in order to obtain products not having an unpleasant odour. The two stages may be combined so as to form a continuous process.—W. H. C.

Petroleum residues; Method of treating and utilising —. V. Kridlo, Prague, Austria-Hungary. *U.S. Pat.* 931,772, Aug. 24, 1909.

"Acid hydrocarbons" [from petroleum] as substitutes for fatty acids, oils, fats, and soaps. *Fr. Pat.* 399,212 See XII.

IV.—COLOURING MATTERS AND DYESTUFFS.

Indigo and its competitors. F. Felsen. *Z. Farben-Ind.* 1909, 8, 215—219, 231—234, 247—252, 263—267.

THE author discusses the various basic, alizarin, substantive and sulphur dyestuffs which have been suggested from time to time as substitutes for indigo, and shows that the latter cannot be surpassed either from the point of view of cost of application or of chemical properties. Derivatives of indigo at present on the market are Dimethylindigo (as Indigo MLB/T Hoechst and Indig. BASF G Badische), monobromoindigo (as Indigo MLB/Hoechst and Indigo BASF/R Badische), mixture mono- and di-bromoindigo (as Indigo MLB/RR Hoechst), dibromoindigo (as Indigo RBN and RB Badische, Indig. MLB/2B Hoechst, and Ciba Blue B Chem. Ind. Base), tetrabromoindigo (as Ciba Blue 2B Chem. Ind. Base), bromindigo FB, Bayer, and Indigo MLB/4B Hoechst and pentabromoindigo (?) (as Indigo MLB/6B Hoechst).

Although some of these are faster to light and chlorine than indigo, they are considerably weaker in dyeing strength. It is shown also that the modern Indanthrene dyestuffs are very much more costly in dyeing than is indigo. The various processes of preparing the indigo vat are discussed as also the mode of application. At the end of the paper the author gives a table showing the relative cost of dyeing yarn with various brands of indigo and with other blue dyestuffs.—J. C. C.

Indigotin; The brominated derivatives of —. A. Binz and T. Marx. Z. angew. Chem., 1909, 22, 1757—1759.

With the displacement of natural indigo by the purer synthetic product the question of indigo analysis has lost somewhat in importance, but the use in practice of mixtures of synthetic indigo and its halogen derivatives, renders it desirable to find some method for the estimation of these compounds. Trials with a method of oxidation led to no useful results and the results obtained with Binz and Kufferath's method (extraction with a mixture of 25 parts of glacial acetic acid and 5 parts of concentrated sulphuric acid) were not reliable. Mono- and dibromo-indigo have only slight (if any) basic properties, and although some analyses showed a high percentage of acid in the precipitated product, the presence of this is due to the amorphous nature of the precipitate rendering the removal of the acid, by washing, a matter of some difficulty. Extraction with various solvents appears to give the best results. Thus, by extracting with alcohol, isatin derivatives are removed; treatment with chloroform removes tribromo-indigo, and by shaking the residue with a mixture of 80 parts of glacial acetic acid and 20 parts of concentrated sulphuric acid, indigo and monobromo-indigo are brought into solution. The proportion of indigo to monobromo-indigo is calculated from the bromine content of the dissolved portion. The residue is dibromo-indigo, which is practically insoluble in the acetic-sulphuric acid mixture.—F. M.

Bixin; Constitution of —. J. F. B. Van Hasselt. Chem. Weekblad, 1909, 6, 480—483. Chem. Zentr., 1909, 2, 624.

BIXIN, the red dyestuff of *Bixa orellana* (annatto) has the composition, $C_{25}H_{34}O_5$; it contains one hydroxyl and one methoxyl group. It melts at 189°C , and when heated in a current of hydrogen at 200°C evolves one molecular proportion of *m*-xylene, leaving a colourless residue. By the action of dilute potassium hydroxide solution on bixin, there are formed first, potassium bixinate, $C_{25}H_{30}O_3(\text{OK})$ (OCH_3), and then dipotassium norbixinate, $C_{25}H_{30}O_2(\text{OK})_2$. The latter when treated with dilute acids yields norbixin, $C_{25}H_{30}O_3(\text{OH})_2$, a bright red, crystalline substance, which decomposes at 240°C , and can be converted into bixin by partial methylation. By the action of zinc dust and glacial acetic acid, bixin and its derivatives yield dihydro-compounds; whilst by the action of bromine, white amorphous, unstable compounds containing 10 atoms of bromine are produced. The author is unable to confirm Zwick's statement (Arch. Pharm., 238, 58) that on heating with steam, bixin yields palmitic acid.—A. S.

Sensitiveness of dyestuffs to light. Von Hübl. See XXI.

PATENTS.

Colouring matters [dyestuffs] of the anthracene series; Manufacture of. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 339, Jan. 6, 1909.

A SULPHONIC acid of Indanthrene Blue, differing from that described in Eng. Pat. 12,185 of 1901 (this J., 1902, 338), is prepared as follows:—1 part of powdered Indanthrene Blue is introduced at 30°C into a solution of 1 part of anhydrous boric acid in 5 parts of sulphuric acid monohydrate. After stirring for several hours, 10 parts of monohydrate are added and the whole is heated for 4—5 hours at 130°C . After cooling, the mass is poured into ice and water, boiled for an hour, filtered, and the residue washed. The dyestuff yields a cornflower blue vat with alkaline hyposulphite (hydrosulphite).—J. C. C.

Indigo; Production of polyhalogenated derivatives of —. Badische Anilin und Soda Fabrik. Fr. Pat. 399,285, Feb. 9, 1909. Under Int. Conv., Mar. 4, 1908.

POLYHALOGENATED derivatives of Indigo are prepared by heating Indigo or its mono- or dihalogen derivatives with bromine to a high temperature in the presence of indifferent agents, whereby the Indigo is maintained in a finely divided condition. Example 1: 140 kilos. of powdered Indigo are heated (temperature of oil-bath: 170°C) and completely dried by means of a current of dry hydrogen, carbon dioxide, or air. 260—270 kilos. of bromine, preferably in the vaporous state, are added, and the mass kept at 170°C for 1—2 hours. Hydrogen bromide and excess of bromine are removed by a current of air and the product is boiled with water and a little sodium hydroxide. A yield of 90 per cent. of tribromo-indigo is thus obtained. Example 2: 140 kilos. of Indigo are finely ground with 400 kilos. of dry salt and the moisture is removed as described above. 350 kilos. of bromine are now added as before (temperature of oil-bath: 200° — 210°C) and the product treated as in the first example. A yield of 90 per cent. of the theoretical amount of tetrabromoindigo is thus obtained.—J. C. C.

Dyestuffs; Manufacture of new —. Farbwerke vorm. Meister, Lucius, und Brüning, Höchst on the Maine, Germany. Eng. Pat. 3758, Feb. 15, 1909. Under Int. Conv., Aug. 31, 1908. Addition to Eng. Pat. 3602 of 1909.

In the process described in Eng. Pat. 3602 of 1909 (see Ger. Pat. 208,968; this J., 1909, 517) it is advantageous to use the nitroarylacyl derivatives of 2:5:7-amino-naphtholsulphonic acid. The diamino-compounds which are obtained on reduction, when developed by means of β -naphthol, yield shades very fast to soap. Example: 25 kilos. of *p*-nitrobenzoyl-*p*-phenylenediamine are diazotised and combined with 40 kilos. of *m*-nitrobenzoyl-2:5:7-aminonaphtholsulphonic acid in alkaline solution. 135 kilos. of crystallised sodium sulphide are now added and the mixture heated to 60 — 65°C until the nitro-dyestuff has disappeared. The resulting dyestuff furnishes red tints on unmordanted cotton, which by diazotisation and development with β -naphthol are rendered fast to washing.—J. C. C.

Xanthopurpurin; Process for preparing —. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 212,697, July 20, 1907.

PURPURIN can be reduced to xanthopurpurin (1,3-dihydroxyanthraquinone) by means of alkaline stannous oxide solutions, but the process is costly. It is now found that complete reduction is obtained by using alkaline solutions of hydrosulphite. In this case the carbonyl groups are not reduced, as is the case when anthraquinone is reduced by hydrosulphite.—T. F. B.

Azo-dyes [dyestuffs]. Wülfling, Dahl und Co., Act.-Ges., Barmen, Germany. Eng. Pat. 4859, Feb. 27, 1909. Under Int. Conv., Feb. 13, 1909.

CLAIM is made for a dyestuff specially suitable for making colour lakes, prepared by combining diazotised 2-naphthylamine-1-sulphonic acid with β -naphthol and abstracting the elements of water from the dyestuff. The new dyestuff is termed "F-anhydride," and it is dark red, whilst the original dyestuff is bright red. The anhydride formation is effected: (1), by treating the ordinary dyestuff with acetic anhydride; (2), by the action of cold concentrated sulphuric acid; (3), by effecting the combination at 40°C ; (4), by combining the diazo-salt and the β -naphthol in the presence of a saturated solution of salt. —J. C. C.

Red chromable dyestuffs; Manufacture of —. L. Cassella und Co., Ges.m.b.H., Frankfurt on the Maine, Germany. Eng. Pat. 8154, April 5, 1909. Under Int. Conv., April 7, 1908.

RED chrome dyestuffs are obtained by combining a diazosulphonic acid such as *p*- or *m*-diazobenzenesulphonic acid with an aminoalcohol ether, diazotising the product, and combining with salicylic or *o*- or *m*-cresotinic acid. An example is given in which diazotised sulphanilic acid

is combined in acid solution with *m*-amino-*p*-cresol ether ($\text{NH}_2 : \text{CH}_3 : \text{C}_2\text{H}_5\text{O} = 1 : 3 : 6$) and the product diazotised and combined with *o*-cresotinic acid in alkaline solution.

—J. C. C.

Dyestuffs; Production of red chrome —. L. Cassella und Co., Ges.m.b.H. First Addition, dated May 26, 1908, to Fr. Pat. 398,980, April 7, 1908 (see Eng. Pat. 8154 of 1909, preceding).

RED chrome dyestuffs are obtained by combining the diazo-sulphonic acids of aminocresol ethers, nitroaminobenzenes or nitroaminophenols or their homologues or analogues with an aminocresol ether, and combining the diazo-compounds of the aminoazo-dyestuffs thus obtained with salicylic or the cresotinic acids. Example 1: *m*-Amino-*p*-cresol ether monosulphonic acid is diazotised and combined with *m*-amino-*p*-cresol ether in hydrochloric acid solution. The product is diazotised and combined with *m*-cresotinic acid in alkaline solution. The resulting dyestuff is a deep brown powder dyeing wool in orange shades which become bluish-red on treatment with bichromate. Example 2: *m*-Nitro-*p*-sulphanilic acid is diazotised and combined with *o*-amino-*p*-cresol ether and the product diazotised and combined with *m*-cresotinic acid: the dyestuff produces orange tints on wool which change to deep garnet red on chroming. Example 3: Nitroaminophenolsulphonic acid ($\text{NH}_2 : \text{NO}_2 : \text{OH} : \text{SO}_3\text{H} = 1 : 3 : 4 : 5$) is diazotised and combined with *m*-amino-*p*-cresol ether and the diazotised product combined with *o*-cresotinic acid. The resulting dyestuff dyes wool scarlet red becoming deep bluish red on chroming.—J. C. C.

Tetrabromindigo; Manufacture of —. Kalle und Co., Akt. Ges., Biebrich on the Rhine, Germany. Eng. Pat. 15,088, June 28, 1909. Under Int. Conv., Aug. 1, 1908.

THE bromination of indigo is advantageously effected in presence of chlorosulphonic acid instead of concentrated sulphuric acid. Example: 15 kilos. of bromine are stirred into 50 kilos. of chlorosulphonic acid, and 5 kilos. of finely powdered indigo are added gradually at the ordinary temperature. The tetrabromindigo is filtered off, pressed, and dried.—J. C. C.

Vat dyestuff. P. Thomaschewski, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 928,891, July 20, 1909.

THE new dyestuff, which is a pyrimidone of the anthracene series, is obtained by condensing 1-amino-4- β -anthriminoanthraquinone with urea. It is a dark red crystalline powder giving a violet blue solution with concentrated sulphuric acid and, with alkaline hyposulphite (hydrosulphite), yields a vat from which cotton is dyed in fast, violet-red shades.—J. C. C.

Azo dyestuff. L. Hesse and O. Günther, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 931,423, Aug. 17, 1909.

CLAIM is made for the dyestuff prepared by combining diazotised aminoazobenzenesulphonic acid with 2-benzoyl-amino-5-naphthol-7-sulphonic acid. The sodium salt is a reddish-brown powder giving a blue solution with concentrated sulphuric acid and dyeing cotton in scarlet shades.—J. C. C.

Azo dyestuff. L. Hesse and O. Günther, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 931,424, Aug. 17, 1909.

CLAIM is made for the dyestuff prepared by combining diazotised 2-naphthylamine-4:8-disulphonic acid with *p*-xylydine, diazotising the product and combining it with 2-benzoylamino-5-naphthol-7-sulphonic acid. The sodium salt is a greenish powder giving a greenish-blue solution in concentrated sulphuric acid and dyeing cotton in dark red shades.—J. C. C.

Anthraquinone; Process for the production of halogenated derivatives of —. Farbenfabriken vorm. F. Bayer und Co., First Addition, dated Jan. 29, 1909, to Fr. Pat. 386,599, Jan. 27, 1908 (this J., 1908, 744).

HALOGENATED nitroanthraquinones are obtained by treating nitroanthraquinone sulphonic acids with halogens or halogenating agents. Example: To a solution of 100 kilos. of sodium 1:5-nitroanthraquinonesulphonate in 4000 litres of water are added 300 kilos. of hydrochloric acid (20 B.). The solution is heated to 90° C., a solution of 100 kilos. of sodium chlorate in 1500 litres of water added and the whole heated at 100° C., until no further precipitation of 1:5-nitrochloroanthraquinone occurs. This substance, when purified by crystallisation from glacial acetic acid forms yellow needles.—J. C. C.

Anthraquinone derivatives and products resulting therefrom; Process of obtaining new —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 400,186, Feb. 9, 1909. Under Int. Conv., Aug. 4, 1908.

MERCAPTANS of the anthraquinone series are condensed with chloroacetyl derivatives of aminoanthraquinones, whereby derivatives of thioglycollic acid are obtained of the general formula, $\text{A.S.CH}_2\text{CO.NH.A}$, where A represents anthraquinone or a derivative of it. The compounds produced furnish vats from which cotton is dyed in deep yellow, red to blue shades. Example: A mixture of 10 kilos. of chloroacetyl-1-aminoanthraquinone, 11 kilos. of anthraquinone-1-mercaptan (sodium salt), and 100 litres of alcohol is heated to boiling under a reflux condenser until no increase in the precipitate formed is noticed. The dyestuff gives with alkaline hyposulphite (hydrosulphite) a vat from which cotton is dyed in fast yellow shades.—J. C. C.

Anthracene compounds; Production of —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 400,500, Mar. 5, 1909. Under Int. Conv., Mar. 23, and April 10, 1908.

NEW anthracene compounds are obtained by treating 1-aminoanthraquinone or its derivatives with acid amides (except urethanes) or by heating 1-acylaminoanthraquinones with ammonia. Example 1: A mixture of 10 parts of 1:4-diaminoanthraquinone and 50 parts of formamide is heated to 180° C. until the mixture becomes yellow. The product is collected and can be crystallised from nitrobenzene. It is probably a dipyrimidine. Example 2: A mixture of 10 parts of 1:4-diaminoanthraquinone, 20 parts of formamide, and 40 parts of phenol is boiled for 1½ hours: an equal volume of alcohol is added and, on cooling, brownish-yellow crystals separate which are probably 4-amino-1-anthrapyrimidine. Example 3: A mixture of 10 parts of 1-aminoanthraquinone, 10 parts of urea and 10 parts of phenol are boiled for 4 hours. The product ($\text{C}_{15}\text{H}_9\text{O}_2\text{N}_2$) is precipitated by adding alcohol: it crystallises from nitrobenzene in yellow prisms. 1-Amino-4-*p*-tolylaminoanthraquinone may be similarly condensed, yielding 4-*p*-tolylamino-1-anthrapyrimidine, the sulphonic acid of which dyes wool violet. Example 4: A mixture of 17 parts of 1-methylamino-4- β -anthriminoanthraquinone (obtained by condensing 1-methylamino-4-aminoanthraquinone with β -chloroanthraquinone), 20 parts of urea, 10 parts of zinc chloride, and 80 parts of phenol is heated until the melt, originally blue, becomes reddish-violet. It is poured into sodium hydroxide solution, the dyestuff filtered off and washed with hot water and dilute hydrochloric acid. It gives a dull blue solution in concentrated sulphuric acid and when precipitated from this solution forms violet flocks which, with alkaline hyposulphite (hydrosulphite), give a vat dyeing cotton in violet-red shades. Example 5: 10 parts of the urethane of 1-aminoanthraquinone are heated with 200 parts of 20 per cent. ammonia in an autoclave to 150° C. The product consists of the anthrapyrimidine described in example 3.—J. C. C.

Anthraquinone derivatives containing nitrogen; Process for preparing —. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 212,436, May 27, 1908. Addition to Ger. Pat. 210,019, May 1, 1908.

IN preparing the condensation products from aminoanthraquinones and succinic acid, described in the

original patent (this J., 1909, 650), the succinic acid may be employed in the form of its anhydride, chloride, bromide, imide, imide, or other derivative which reacts readily. In some cases it is advantageous to add to the reaction mixture a condensing agent, such as boric acid, zinc chloride, etc.—T. F. B.
